Age and hemispheric differences in transcallosal inhibition between motor cortices: an ipsilateral silent period study

Travis Davidson¹,³ and François Tremblay¹,²,³*

Abstract

Background: In this study, we investigated age and hemispheric differences in transcallosal inhibition (TCI) in the context of active contraction using the ipsilateral silent period (iSP). We also examined whether age-related changes in TCI would be related to corresponding changes in manual performance with age. Participants consisted of right-handed individuals from two age groups (young adults, n=13; seniors, n=17). The iSP was measured for each hemisphere using suprathreshold TMS pulses delivered over the primary motor cortex ipsilateral to the maximally contracting hand while the homologue muscles of the opposite hand were lightly contracting (~15% of the maximum). Manual performance was assessed bilaterally for both grip strength and fine dexterity.

Results: Our results yielded two main findings. First, TCI measures derived from iSP were strongly influenced by age, whereas differences between hemispheres were only minor. Second, correlation analyses revealed that age-related variations in TCI measures were related to changes in manual performance, so that left-to-right TCI correlated with right hand performance and vice-versa for the opposite hand/hemisphere.

Conclusion: Overall, these results concur with other recent reports indicating that mutual inhibition between motor cortices tends to decline with age. In this respect, our observations are in line with the notion that the balance of normally predominantly inhibitory interactions between motor cortices is shifted toward excitatory processes with age.

Background

Coordination of movements relies on both the activation of each independent hemisphere and the communication between hemispheres which is mediated via the corpus callosum [1]. This transcallosal pathway is essential for the interhemispheric transfer of perceptual, sensory and motor information underlying complex and integrated behaviors [2]. Although transcallosal connections can be facilitatory, mutual inhibition appears to be the primary mode of action between the two primary motor cortices [3]. This mutual inhibition has been shown to be finely modulated depending on task demands, unilateral actions leading to increased inhibitory drive from the active hemisphere, whereas bilateral actions lead to more balanced inhibition between hemispheres allowing for coordinated actions of the two extremities [4,5]. In the primary motor cortex (MI), interhemispheric inhibition can be assessed non-invasively with transcranial magnetic stimulation (TMS) using either paired-pulse paradigms or via the ipsilateral silent period (iSP) [6]. With paired-pulse paradigms, the target hemisphere is first conditioned by applying suprathreshold TMS on the opposite hemisphere at short (8–12 ms) or long (e.g., 40 ms) inter-stimulus intervals leading to two corresponding periods of inhibition of test motor evoked potentials (MEPs), i.e. short-latency (SIHI) and long-latency (LIHI) interhemispheric inhibition. The iSP assesses transcallosal inhibition by applying focal TMS to the motor cortex ipsilateral to the test hand while the target muscle is activated voluntarily, leading to a brief interruption of the ongoing muscle activity [7]. This interruption of voluntary muscle activity is thought to reflect transcallosal inhibition (TCI) mediated by the MI.
opposite to the one being active for maintaining the contraction [7]. As stressed by Chen et al. [8], although SIHI/LIHI and iSP both reflect interactions between motor cortices, they should be considered complementary rather than equivalent measures of TCI since their effects appear to be mediated by different neuronal populations.

While TMS investigations have highlighted the critical role of interhemispheric inhibition in the acquisition and transfer of motor skills [9], there is still limited information as to how this process changes as people advance in age. Indirect evidence of changes in interhemispheric inhibition with age comes from observations of difficulties experienced by older adults in bimanual tasks along with the presence of motor overflow during performance of unimanual actions [reviewed in 10]. This is paralleled by reports from functional neuroimaging studies showing that task-related activation patterns in sensorimotor areas are typically less lateralized and more widespread in older adults than in young adults [11]. Such changes in brain activation patterns are consistent with reports of structural alterations in the corpus callosum with age affecting its integrity in terms of the quantity and quality of white matter [12,13]. As suggested by Seidler and colleagues [10], such observations point to a shift in the balance of mutual inhibition between motor cortices with age towards excitatory processes. In agreement with this view, Talelli et al. [14] reported that the degree of LIHI from the left MI to the right MI during right hand grip was progressively reduced with advancing age, there was even a switch from inhibition to facilitation in the very old participant. Interestingly, the age-related reduction was not observed for SIHI, a differential effect the authors ascribed to putative physiological differences between SIHI and LIHI. In line with this, a recent investigation by Fling and Seidler [15] using the iSP as an index of transcallosally-mediated inhibition associated with voluntary contraction, also failed to detect age differences although young participants tended to show longer iSP durations than old participants. Thus, although observations from behavioral and neuroimaging studies seem compatible with an age-related shift in the balance of mutual inhibition between motor cortices, recent findings from TMS studies remains controversial in this regard.

Another related controversial topic with regard to hemispheric interactions pertains to laterality issues associated with manual asymmetries. Given anatomical and physiological evidence pointing to a leftward asymmetry in the organization of the hand motor representation in strong right-handers [16], one would expect that the balance of inhibition between motor cortices would favour the dominant (left) over the non dominant (right) hemisphere in most individuals. Surprisingly, very few TMS studies have examined this issue specifically. In line with the existence of a leftward asymmetry, early investigations by Netz et al. [17] showed that levels of SIHI from the dominant hemisphere was greater than that elicited from the non-dominant hemisphere in right-handers. More recent investigations, however, showed that such asymmetries in interhemispheric inhibition observed in the resting state are not necessarily present in the active state [18]; highlighting the importance of examining interhemispheric interactions in the context of voluntary contraction.

In the present study, we investigated mutual inhibition between motor cortices using the iSP as an index of transcallosally mediated inhibition in healthy young and senior adults. We first asked whether differences existed between the dominant and non dominant MI in strong right-handed participants and whether these differences were affected by age. Then, we asked whether age-related variations in the strength of TCI from one hemisphere would be related to changes in performance of the contralateral hand with age.

**Results**

**Manual performance and corticomotor excitability**

Right-left differences in manual performance and in basic measures of corticomotor excitability are described in Table 1 for the two groups. As expected, both young and senior participants exhibited significantly better performance in terms of dexterity and grip strength with their right dominant hand (Young, $t_{12}>3.75$, $p<0.003$; Senior, $t_{16}>3.52$, $p<0.01$) than in right hemisphere; a difference that reached significance only in the senior group ($t_{15}=3.01$, $p=0.008$). Apart from this difference, the other paired comparisons revealed no significant right-left differences in either MEP characteristics (amplitude and latency) or in contralateral silent period (cSP) duration in both groups. Finally, as for manual performance, age differences were also clearly evident in corticomotor excitability, all measures pointing to a decrease (e.g., elevated rMTs) in the left hemisphere (i.e., right hand in Table 1) than in right hemisphere; a difference that reached significance only in the senior group ($t_{15}=3.01$, $p=0.008$).

Apart from this difference, the other paired comparisons revealed no significant right-left differences in either MEP characteristics (amplitude and latency) or in contralateral silent period (cSP) duration in both groups. Finally, as for manual performance, age differences were also clearly evident in corticomotor excitability, all measures pointing to a decrease (e.g., elevated rMTs) in the left hemisphere (i.e., right hand in Table 1) than in right hemisphere; a difference that reached significance only in the senior group ($t_{15}=3.01$, $p=0.008$).

**Age and hemispheric differences in ipsilateral inhibition**

Variations in measures of ipsilateral inhibition with respect to age and hemisphere are illustrated in Figure 1. Note that the final analysis of iSP data excluded two senior participants. The first case had incomplete data due...

to poor tolerance for TMS at high intensity. The second
case was an outlier, as detected with the Grubb’s test
(Z=3.67, p<0.01), with very long iSPs. Two main
observations can be made from inspection of Figure 1. First,
only relatively small differences were observed between
hemispheres in the two age groups. This is evident in
Figure 1A showing examples of iSP recordings obtained
from each hemisphere in a typical senior and young
participants. Second, age had a major impact on TCI with
seniors showing delayed onset latency of transcallosal
inhibition (LTI), decreased iSP area and prolonged
transcallosal conduction time (TCT). The impact of age
can be easily appreciated by looking at the mean vari-
ations in LTI, iSP area and TCT measured in each age
group, as illustrated in Figure 1 (B, C and D). The
ANOVA confirmed that “hand/hemisphere” had little in-
fluence on iSP measures, with only a marginal trend
noted for iSP area (F1,26=3.8, p=0.06) owing to the
interhemispheric difference observed in the young group
(Figure 1C). The large influence of “Age Group” on TCI
measures (F1,26>20, p<0.001) was also confirmed, this
factor alone accounting for >40% of the total variance
observed in LTI, iSP area and TCT measures. For all
TCI measures, no interactions were found between
“hand/hemisphere” and “Age Group” (F1,26<1, p>0.49).

The large “Age” effect found in the primary analysis
prompted a secondary analysis to better delineate the
impact of this factor and also to address possible influ-
ences arising from age differences in corticomotor exci-
tability. For this secondary analysis, all right and left
TMS measures obtained in each participant were aver-
ged to get single mean values. Then, chronological age,
rMT, MEP amplitude, MEP latency and cSP duration
were entered as co-variates into univariate analyses of
covariance (ANCOVA) to examine their respective im-
 pact on each measure of TCI (i.e., LTI, iSP area and
TCT). This series of ANCOVAs confirmed the signifi-
cant impact of chronological age (F1,22=4.5, p<0.05), this
factor alone accounting for respectively 17%, 24% and
23% of the variance in LTI, iSP area and TCT measures.
Besides a significant effect of MEP latency on LTI mea-
sures (F1,22=11.1, p=0.002), which was expected given
that LTI depends to a large extent on MEP latency, no
other co-variates had a significant effect on measures of
TCI (F1,22<3.6, p>0.07).

Relationships between transcallosal inhibition and
manual performance
The results of the correlation analysis examining the
relationships between measures of interhemispheric
inhibition and age-related variations in unimanual per-
formance in the right and left hands are described in
Table 2. As evident in the Table 2, the associations were
generally stronger for the dexterity than for the grip
strength test and this for both hands. The nature of
these relationships can be further appreciated in Figure 2.
It can be seen, for instance, that age-related variations in
LTI derived from each hemisphere were strongly related
to dexterity of the contralateral hand; delayed onset be-
ing associated with slower performance (Figure 2A).
Likewise, age-related variations in iSP area explained a
significant proportion of the variance observed in
contralateral grip strength, especially for the left hand
with right to left TCI (Figure 2B).

Discussion
In the present study, we investigated age and hemispheric
differences in mutual inhibition between motor cortices
during voluntary activation using the iSP to probe TCI.
Two main findings emerge from our observations. First,
TCI indices derived from iSP characteristics (i.e., LTI, iSP
area and TCT) were strongly influenced by age differ-
ences, whereas differences between hemispheres were only
marginal. Second, correlation analyses revealed significant
relationships between indices of TCI derived from each hemisphere and performance of the contralateral hand in dexterity and grip strength tests, so that left-to-right TCI correlated with right hand performance and vice-versa for right-to-left TCI and left hand performance. In the following discussion, we address the significance of these findings for the study of aging and its impact on motor systems.

**Age and hemispheric differences in TCI**

Contrary to evidence suggesting an asymmetry in the balance of mutual inhibition in favor of the dominant MI in right-handed individuals [17,19,20], only minor differences in TCI were found between the two hemispheres in our two groups of participants. In this respect, our results appear consistent with those of De Gennaro et al. [3], who found no difference in interhemispheric inhibition between the two hemispheres in resting state using bifocal TMS in young adults. Our observations for the senior group are also in line with those of Lewis & Perrault [18] who also failed to detect differences in paired-pulse SIHI in their group of healthy senior adults, who served as controls for stroke patients. Interestingly, the absence of hemispheric asymmetry reported in Lewis & Perrault’s study was evident only when the target hand (contralateral to the test hemisphere) was active, irrespective of whether the ipsilateral hand was active or not. In the present study, the fact that iSP was tested during concurrent contraction of both hands might have been critical in attenuating possible asymmetries in the level of mutual inhibition in relation to manual dominance. It remains that the issue of hemispheric asymmetries in relation to manual dominance remains a controversial topic in the TMS literature.

![Figure 1 Examples of ipsilateral inhibition and mean group differences](image)

*Figure 1 Examples of ipsilateral inhibition and mean group differences.* A. Examples of rectified and averaged EMG traces (n=5 trials) depicting ipsilateral silent periods elicited in response to transcranial magnetic stimulation (TMS) in two participants, young and senior. As illustrated, several measures of transcallosal inhibition could be derived from iSP recordings. The latency of transcallosal inhibition (LTI) was computed as the time interval between the cortical stimulus and the iSP onset, which was determined as the first sustained decline in EMG activity when compared to mean pre-stimulus level. The duration of transcallosal inhibition (DTI) was estimated as the time interval between the iSP onset and offset, which was determined as the point where the EMG activity returned to pre-stimulus level. Finally, the depth of ipsilateral inhibition was estimated by calculating the iSP area, as depicted by the blank area delimited by the two vertical dotted lines and below the horizontal line in the recordings. Note that timing measurements are given only for illustrative purposes, as the real estimates were derived from a trial-by-trial analysis. B, C and D. Mean variations (± 1 SD) in measures of ipsilateral inhibition (B, LTI: Latency of transcallosal inhibition; C, iSP area: ipsilateral silent period area, D, TCT: transcallosal conduction time) derived from each hand/ hemisphere for the two groups of participants. Note again the major differences between age groups as indicated by the asterisks (p<0.001).

Figure 2 Illustrations of relationships found between measures of transcallosal inhibition (TCI) derived from each hemisphere and age-related variations in unimanual performance in dexterity (A) and strength (B) tests. In both A and B, the relationships are given with respect to the direction of TCI induced from one hemisphere to the other and performance of the contralateral hand controlled by the stimulated hemisphere; so that left to right TCI is correlated with performance of the right hand. A. Relationships between onset latency of TCI and contralateral dexterity, as measured with the Grooved Pegboard Test after log-transformation of timed performance. B. Relationships between the ipsilateral silent period area (iSP) and contralateral grip strength, as measured with a pinch dynamometer. Note that correlational analysis omitted two subjects in the senior group, one with incomplete data and one detected as an outlier.
[e.g., see 21] and more research is needed with larger groups of right- and left-handers to address the question.

Contrasting with the relatively minor difference found between hemispheres, a major difference was found between age groups, senior participants showing delayed LTI, prolonged TCT and reduced iSP area when compared to young participants. Given that our group of seniors exhibited signs of decreased corticomotor excitability, it is possible that the observed age difference in TCI might have reflected impaired motor activation or peripheral nerve dysfunction. This possibility seems unlikely, however, for several reasons. First, with regard to motor activation, the work of Giovannelli et al. [22] has clearly demonstrated that TMS-induced ipsilateral inhibition is little affected by the intensity of contraction in the test hand, the most important factor being rather the presence of light activity in the opposite hand. During testing, all our participants, and especially seniors, were encouraged to produce their maximum effort in the ipsilateral hand, while lightly contracting the other hand. Thus, by basing our assessment on Giovannelli’s method, we made sure that conditions would be optimal to elicit ipsilateral inhibition in each age group, in spite of individual variations in muscle activation. Second, as demonstrated by our secondary analysis (ANCOVAs), age-related variations in various indices of corticomotor excitability had little influence on measures of ipsilateral inhibition. In fact, the only significant interaction found was between LTI and contralateral MEP latency, which was expected. However, the computation of TCT, which largely removes the influence of MEP latency, showed that age differences were still highly significant. To summarize, while our seniors exhibited typical signs of corticomotor aging [e.g., 23], these changes could hardly account for the large age effect observed on iSP measures; pointing to central alterations in TCI as the primary cause.

In fact, our observations appear to be congruent with the proposal of Seidler’s group [10] that there is a shift with age in the balance of mutual inhibition between motor cortices towards excitatory processes. However, as noted earlier, these investigators [15] found only a trend when comparing the strength of ipsilateral inhibition in young and old adults. Their observation that young adults tended to show deeper levels of ipsilateral inhibition than older adults seems consistent with the age difference reported here. In more direct line with our results, Boudrias et al. [24] observed a strong age effect when comparing measures of interhemispheric inhibition derived from bi-focal TMS in young and older adults. In their study, a clear distinction was seen between young and older adults in that most seniors showed evidence of transcallosal facilitation rather than the typical inhibition. In the same vein, McGregor et al. [25] found that measures of ipsilateral inhibition were significantly reduced in older subjects when compared to young. Interestingly, the largest reductions were seen in the group of sedentary seniors, where iSP durations were on average 50% shorter than in young adults; a range comparable to the averaged reduction in iSP area reported here (57%). In physically active seniors, the reduced ipsilateral inhibition was less pronounced (~25%), which led McGregor et al. to conclude that engaging in regular physical activity could help to maintain levels of interhemispheric inhibition. Although we did not specifically control for activity level in our study, it is worth noting that the outlier senior who showed exceptionally long iSP duration (see Results) was also highly active as judged by self-report. It would be interesting for future studies to investigate how interactions between advancing age and levels of physical activity influence hemispheric interactions, but the small sample size used in the present study precludes any conclusion in this regard. Nevertheless, both the present findings and the results of recent TMS studies concur with the notion that transcallosally mediated inhibition becomes less efficient with age in line with reports describing structural alterations in the integrity of callosal fibres between motor cortices with advancing age [15,24,26].

Regarding the physiological mechanisms underlying the observed changes in iSP measures with age, the reduced iSP area points to a decrease in the excitability of ipsilateral transcallosal inhibitory neurons. Such a decrease would be consistent with reports of age-related reductions in the excitability of local inhibitory circuits mediating short-interval intra-cortical inhibition (SICI) [27] and short-latency afferent inhibition [28] reported in the motor cortex of seniors. As shown by Avenzino et al. [29], local interneurons involved in transcallosally mediated inhibition share common properties with those controlling excitability of pyramidal tract neurons; and thus, any alterations in intra-cortical excitability with age could also affect inhibitory connections between motor cortices. In parallel, the delayed LTI and prolonged TCT found in seniors are consistent with reports of structural alterations in callosal connectivity between motor cortices with age, as stated earlier. In fact, a growing body of evidence [12,30] is now emerging linking preserved task-related functional connectivity between hemispheres in seniors with integrity of transcallosal connections. Indeed, as suggested by our correlational analysis, integrity of transcallosal connections seems to be important in allowing older adults to maintain certain levels of performance, as discussed below.

**Relationship between ipsilateral inhibition and manual performance**

The result of our correlation analysis revealed significant relationships between our different measures of TCI in
each hemisphere and performance of the contralateral hand, so that left to right TCI (left hemisphere stimulated) correlated with right hand performance and vice versa for the left hand. Interestingly, these associations were particularly strong for the dexterity task, which is consistent with the purported role of TCI in preventing motor overflow when task demands require fine unilateral control of one hand [31]. While correlations with grip strength were not as strong, good quality relationships were still found, for example, between iSP area and left hand; suggesting a role of TCI in unimanual force production. In line with this, Fling and Seidler [4] recently reported an inverse relationship between measures of ipsilateral inhibition and the ability of young individuals to suppress motor activity in the resting hand (i.e., motor overflow) during a unimanual force production task. Although we did not monitor motor activity in the resting hand during our tests of manual performance, our observations on the association between measures of TCI and manual performance are consistent with those of Fling and Seidler with regard to the role of TCI in allowing fine independent control of unimanual performance. In a related study from the same group of investigators [13], the association between functional motor activation and performance of a precision task with the dominant hand was examined in young and old adults. Much like in the present study, the authors found that increased ipsilateral motor recruitment (and presumably less efficient TCI) was associated with poorer task performance. The fact that this association was found only for the older group and not in younger subjects does not invalidate the comparison with the present findings since both their results and ours converge to show that proper levels of TCI is an important factor in leading to fine motor performance in the context of precision tasks, especially as people advance in age. In fact, there is ample evidence from TMS studies that levels of intra- and interhemispheric inhibition are critical for the performance of fine motor tasks [14,32-34]. With regard to aging specifically, the observation that our group of seniors exhibited various levels of impaired ipsilateral inhibition and that these impairments were in part reflected in their dexterity performance would be consistent with other studies in which deterioration in motor performance and in inter-limb coordination with age was associated with a decreased ability to modulate inhibition at the central level [14,34-36].

Conclusion
The present study examined age and hemispheric differences in mutual inhibition between motor cortices using the iSP as a marker of transcallosally mediated inhibition. Consistent with previous studies, we report a major difference with regard to age, whereas differences between hemispheres were only marginal. In addition, we show that measures of TCI derived from each hemisphere correlated well with age-related variations in manual performance of the contralateral hand. Overall, these results appear congruent with the hypothesis proposed by Seidler and colleagues [10] suggesting a shift with age in the overall balance of normally predominantly inhibitory interhemispheric interactions toward excitatory processes. Possible limitations of the present study include the small number of participants in each age group and the fact that older participants were considered as active seniors, which may not be representative of the population of seniors in general.

Methods
The study procedures were approved by the Research Ethics Board at the Bruyère Research Institute, Ottawa, Ontario, Canada. Written informed consent was obtained prior to participation from all participants in accordance with the Declaration of Helsinki. All assessments were performed in a controlled laboratory environment. Each participant received a small honorarium for his or her participation.

Participants
Two groups of participants, young and senior were recruited for this study. The young group (n=13) was recruited from the student population at University of Ottawa, whereas the senior group (n=17) was recruited from the community in the Ottawa-Gatineau area. All participants were right-handed, as determined by the Edinburgh Handedness Inventory [37]. Prior to the experimental session, all participants completed a medical questionnaire to determine their general health status and to ensure that there were no contra-indications to TMS or antecedents of conditions likely to affect their performance in the tests. In addition, sensory function of the hand was assessed using a Rydel-Seiffer tuning fork to rule out the presence of undiagnosed neuropathies. All participants exhibited vibration thresholds in line with their norms for their age range [38]. The demographic characteristics of the participants are listed in Table 1.

Manual performance: Grooved Pegboard Test and pinch strength
For manual performance, participants were comfortably seated in front of a table. All tests were applied bilaterally and administered by the same experimenter (TD). The order of testing with each hand was determined randomly before the testing session. Manual dexterity was assessed with the grooved pegboard test (GPT, Lafayette Instr, IN 47903), which consists of inserting pegs
Magnetic stimulation was delivered via a Rapid2 stimula-
threshold (rMT)
Transcranial magnetic stimulation and resting motor
activity was recorded using
Electromyographic (EMG) activity was performed at the end of the testing session, after neuro-
associated with fatigue, the strength test was always
imal activation in the FDI. To avoid any interference
for each hand with a 60 s rest between trials. The aver-
age provided a measure of pinch strength and of max-
imal activation in the FDI. To avoid any interference
associated with fatigue, the strength test was always
performed at the end of the testing session, after neuro-
physiological testing was completed.

Electromyographic recordings
Electromyographic (EMG) activity was recorded using
10-mm auto-adhesive surfaces electrodes (Ag/AgCl, Kendall Medi-Trace’ 130) placed over the FDI mus-
cles of each hand using a tendon-belly montage. EMG
signals were amplified and filtered with a time con-
stant of 10 ms and a low-pass filter of 1 kHz (AB-
621G Bioelectric amplifier, Nihon-Kohden Corp., CA
92610). Signals were digitized at rate of 2 kHz (BNC-
2090, National Instrument Corp.) and further relayed
to a laboratory computer running custom software to
control acquisition.

Transcranial magnetic stimulation and resting motor
threshold (rMT)
Magnetic stimulation was delivered via a Rapid2 stimula-
tor (Magstim Co. Dyfed, UK) connected to a figure-eight
coil (90 mm outer loop diameter). All testing was
performed with the participants comfortably seated in a
recording chair. Participants were fitted with a
Waveguard TMS compatible cap (ANT North America
Inc, WI 53719) to allow for consistent coil placement. A
U-shaped neck cushion was also used to restrain head
movements and prevent neck fatigue. TMS testing ses-
sions began by first determining the “hotspot” for the
FDI and then by determining the rMT for the stimulated
hemisphere. This procedure was performed sequentially
on each hemisphere with the order of testing between
the two alternating between participants. To determine
the optimal site to evoke MEP’s in the contralateral tar-
get muscle (FDI), the approximate location of the hand
motor area on the stimulated hemisphere was explored in
1-cm steps until reliable MEP’s could be evoked. This
site was then marked with a red dot to ensure consistent
coil positioning. After localization of this stimulation
“hotspot”, the rMT was determined using the procedure
described by Mills and Nithi [39]. Starting from
suprathreshold intensity, the stimulation intensity was
gradually decreased in 1% steps until no MEP’s could be
evoked in 10/10 consecutive trials (lower threshold).
Then, the intensity was increased in 1% increments to
find the minimal intensity that would produce reliable
peak-to-peak amplitude MEP’s of at least 50 μV for 10/
10 consecutive trials (upper threshold). The rMT was
defined for each participant as the median intensity be-
tween the upper and lower threshold values. EMG was
continuously monitored on an oscilloscope, at high gain
(0.1 mV/div), to ensure the absence of any muscle activ-
ity during the procedure. As mentioned above, the same
procedures were repeated for the opposite hemisphere.

Contralateral and ipsilateral silent period (cSP/iSP)
The cSP and iSP were measured concurrently using the
approach described by Giovannelli et al. [22], which
involved maximal contraction of the hand ipsilateral to
the stimulated hemisphere coupled with light contrac-
tion of the contralateral hand. As shown by these au-
thors, voluntary activation of the contralateral hand,
irrespective of the level of contraction significantly
prolongs the iSP in the test hand when compared to
rest and this, without affecting the level of background
EMG in the ipsilateral hand. For cSP/iSP testing, partic-
ipants were instructed to press as hard as they could on
the pinch dynamometer using the thumb and index fin-
gers with one hand, while lightly squeezing a soft exer-
cise ball with their opposite hand. The latter contraction
corresponded, on average, to ~15% of the maximal vol-
untary contraction in both age groups. Participants were
trained to maintain the contractions for 3 s in sync with
a tone (550 Hz) generated by the computer. The subjects
were told to focus on the maximally contracting hand
ipsilateral to the stimulation and were given verbal feed-
back to maintain contraction. In each trial, TMS was de-
ivered on the hemisphere ipsilateral to the maximally
contracting hand at 2 s in the course of the trial using
an intensity equivalent to 120% of the rMT. The inter-
trial interval was 10–15 s. Short pauses were allowed to
prevent fatigue. Five trials were performed on each
hemisphere, the order of testing between hemispheres
alternating between participants. A schematic representa-
tion of the testing paradigm for the cSP/iSP assess-
ment is provided in Figure 3.

TMS data analysis
Data from the cSP/iSP trials were analyzed off-line from
visual inspection of stored EMG traces using custom
software. All visual analyses were performed by the same
investigator (TD) using numerically coded files, which
were saved separately from the demographic data, to allow for blinding with respect to the age of the participant. Visual analysis of silent periods has been shown to have good inter and intra-rater reliability [40,41]. For cSP measures, EMG traces obtained from the contralateral hand were examined individually to determine the duration of the SP and measure the characteristics of the associated MEP in terms of amplitude (peak to peak) and latency. The cSP duration was determined as the time from the MEP onset till the first sign of EMG recovery. Mean values were computed by averaging individual trials. The same approach was used to analyze iSP trials using EMG traces obtained from the ipsilateral hand. For iSP measures, each individual file was analyzed twice with at least one week interval between runs to ensure intra-rater reliability. In each file, two main indices of TCI were derived from the EMG trace of the ipsilateral hand. First, to get an index of the interhemispheric transfer time, the onset latency of transcallosally mediated inhibition (LTI) was measured. The LTI was defined as the time point after iSP onset at which the EMG level returned to the mean level. The reliability analysis showed a strong to very strong level of agreement, as reflected in intra-class correlation coefficients, between the two set of measurements for both the LTI (right hand, 0.93; left hand, 0.97) and iSP area measures (right hand, 0.82; left hand, 0.80). Individual examples of EMG traces analyzed to derive iSP measurements are shown in Figure 1A for a participant in each age group. Finally, as a co-result of this analysis, we derived a third index of TCI by computing the transcallosal conduction time (TCT), i.e., the duration of the stimulus transfer to one hemisphere to the other, by subtracting the MEP latency obtained from the contralateral hand from the iSP onset latency (i.e., LTI, see Figure 3).

The statistical analysis was performed in three steps. First, right-left differences in manual performance and in basic measures of corticomotor excitability were examined in each age group with paired t-tests. For these paired comparisons, the significance level was set at P<0.01 to reduce the risk of type I error owing to multiple comparisons. The second step consisted of examining variations in each index of TCI (LTI, iSP area and TCT, respectively) using analyses of variance (ANOVA) for repeated measures with “Hand/Hemisphere” as the within-subject factor and “Age Group” as the between-subjects factors. For this analysis, the significance level was set at P<0.05 to detect main effects and interactions. The final step consisted of examining relationships between manual performance and measures of TCI using Pearson’s correlation. For these analyses, timed performance for the dexterity test (i.e., GPT) was log transformed to normalize the distribution which was skewed owing to the presence of participants in the senior group (4/17) with very slow performance (>120 s). The significance level for the correlations was set at P<0.05. All statistical tests were performed using SPSS software version 17.0 for Windows® (GraphPad Software, San Diego California USA, www.graphpad.com).

**Abbreviations**

ANOVA: Analyses of variance; DTe: Duration of transcallosal inhibition; EHI: Edinburgh inventory index; EMG: Electromyography; FDI: First dorsal interosseous; GPT: Grooved pegboard test; iSP: Ipsilateral silent period; IS area: Area under the curve during the ipsilateral silent period; LH: Left hand; LIHI: Long-latency interhemispheric inhibition; LTI: Latency of transcallosal inhibition; MEP: Motor evoked potential; MI: Primary motor cortex; RH: Right Hand; rMT: Resting motor threshold; SIHI: Short-latency interhemispheric inhibition.
inhibition; TCI: Transcallosal inhibition; TCT: Transcallosal conduction time; TMS: Transcranial magnetic stimulation.

Competing interests
The authors declare that they have no competing interests.

Authors’ contributions
TD assisted with the study design, carried out the data collection, analyzed all data, and drafted the manuscript. FT conceived the study, aided with data collection and in drafting and editing of the manuscript. All authors read and approved the final manuscript.

Acknowledgments
The authors wish to thank all participants for their time and patience during testing. Part of this work served for the partial fulfillment of a Master of Sciences in Human Kinetics by Travis Davidson. Travis Davidson received a testing. Part of this work served for the partial fulfillment of a Master of
