Abstract

Aims: This study aims to investigate the biomechanical properties of the posterior eye using the shear wave elastography (SWE) in increased intracranial pressure (ICP) patients and healthy subjects. Material and methods: This study enrolled 54 healthy subjects and 54 patients with increased ICP, including 29 patients with space-occupying lesions (SOLs) and 25 patients with intracranial haemorrhage (ICH). Optic nerve sheath diameter and the stiffness of the optic nerve head, peripapillary sclera and optic nerve were evaluated. Results: Patients with increased ICP had a significantly higher optic nerve sheath diameter, Young’s modulus of optic nerve head, and Young’s modulus of peripapillary sclera than healthy subjects (p<0.01 for all). The optic nerve sheath diameter, Young’s modulus of optic nerve head and Young’s modulus of the peripapillary sclera were similar between the SOLs group and ICH group (p>0.05 for all). Young’s modulus of the optic nerve in the ICH group was similar to the control group (p>0.05), whereas the SOLs group had higher Young’s modulus of optic nerve comparing the control group (p<0.05). Conclusion: The stiffness of the optic nerve head and peripapillary sclera were higher in patients with increased ICP than healthy subjects, and the optic nerve stiffness of SOLs patients was the highest in all subjects. The SWE could provide a quantitative analysis of the posterior eye’s biomechanical properties and help the clinic diagnose the degree of visual impairments.

Keywords: optic nerve head; sclera; optic nerve; shear wave elastography; intracranial pressure

Introduction

The cranial cavity of a healthy adult is a constant and enclosed space. The volume of all components in the cranial cavity keeps constant in a dynamic balance state [1]. Increased components, such as space-occupying mass and haemorrhage in the cranial cavity, can upset the balance and lead to increased intracranial pressure (ICP). The optic nerve is surrounded by an optic nerve sheath, which is contiguous with the meninges of the brain. The optic nerve sheath’s subarachnoid space directly communicates with the intracranial subarachnoid space [2]. As a consequence of this structure, intraorbital subarachnoid space is submitted to the same pressure as the intracranial subarachnoid space [3].

Common ocular signs and symptoms of increased ICP include papilledema, optic nerve atrophy, transient obscuration, various types of visual field defects and blindness [4-6]. In patients with space-occupying lesions (SOLs), up to 50% of them present with ocular signs or symptoms [5]. In patients with intracranial haemorrhage (ICH), 55.6% of them present with papilledema and 15% present with visual disturbances [6].

In a dog model, Morgan et al found that elevation in ICP could directly impact the displacement of optic nerve head tissues [7]. Brodsky et al reported that the posterior sclera experiences change in cases with increased intracranial pressure [8]. Nusbaum et al [9] found that sustained ICP elevation resulted in retinal ganglion cell loss and optic nerve degeneration in mice.
The posterior eye is a complex biomechanical structure. The optic nerve and peripapillary tissues, including the optic nerve head and peripapillary sclera, are critical for visual function. Biomechanical change of these tissues is thought to play an essential role in visual impairments [10]. However, research on the peripapillary tissue’s biomechanical properties mainly rely on experimental animals [7,9,11] and computational models [12,13]. The degree of optic nerve impairment is mainly reflected by the morphology parameter cup-to-disc ratio in clinical practice. Cells and tissues are sensitive to biomechanical changes [14]. However, the inaccessibility of the posterior eye has made in-vivo and quantitative analysis of its biomechanical properties challenging.

Shear Wave Elastography (SWE) is a new ultrasonographic imaging technique that provides quantitative information about tissue elasticity in real-time. Focused acoustic radiation force generated by the transducer is applied to local tissue and produces displacement inside the tissue, causing the propagation of shear waves within the selected region [15]. As the shear waves propagate, the ultrasound system tracks the shear wave speed $C_s$ and automatically computes Young’s modulus $E$ based on the mathematical equation $E = 3\rho C_s^2$ in which $\rho$ represents tissue density [16]. The Young’s modulus is directly related to the tissue’s biomechanical properties [15]. The harder the tissue, the faster the speed of sound and, correspondingly, the higher Young’s modulus.

This study aimed to quantitatively analyse the biomechanical properties of the posterior eye using SWE and assess its response to increased ICP insults.

Material and methods

Participants

This prospective study was conducted between May 2020 and October 2020 in the First Affiliated Hospital of Chongqing Medical University. Fifty-four healthy subjects and 54 patients with increased ICP, including 29 patients with SOLs, 25 patients with ICH were enrolled and divided into three groups: the control group, SOLs group and ICH group. The study was approved by the Ethics committee of our hospital and was designed in accordance with the Declaration of Helsinki. All participants were informed of their participation in the study and signed informed consent.

The increased ICP diagnosis was based on the invasive measurement of ICP (more than 15 mmHg) [17] with an inserted intraparenchymal catheter (Codman Microsensor Kit). Subjects under 18 years and those with ocular diseases (e.g., glaucoma, trauma, tumour, inflammatory disease) or with a history of ocular surgery were excluded.

Ultrasonographic examination

All ultrasound images were acquired by the Resona 7T ultrasound scanner (Mindray, Shenzhen, China) with a linear probe (L11-3U). All ultrasound images acquisitions and measurements were performed by a single explorer with 3 years of ultrasound experience. Before the study began, the explorer had received training in ultrasound elastography technique by an expert radiologist. Subjects were scanned in a supine position with eyes closed. Since the intraorbital subarachnoid spaces of the two eyes are subject to the same pressure changes, we assumed that the pathological changes of two eyes could be expected to be equivalent. One eye of each subject was selected randomly. The probe was placed perpendicularly over the eyelid through a thick layer of gel with no pressure on the eyeball.

The optic nerve was identified as a hypoechoic banded structure and surrounded by the hyperechoic optic nerve sheath. After optic nerve sheath images were recorded, the SWE was performed. During the elastography examination, grayscale and SWE images were displayed simultaneously as the dual-screen mode in real-time. The probe was held still with no pressure exerted to the eyeball until acquired stable images, then static images were stored digitally for later analysis. The motion stability (M-STB) index was applied to monitor the motion interference induced by the subject’s respiration or operator’s movement in real-time. M-STB index displayed on the top right corner of the screen and evaluated by stars; a reliable image should display greater than or equal to four green stars. The optic nerve sheath and elastographic images of each subject were sequentially obtained at least 3 times. All images were stored for later measurements.

The optic nerve sheath diameter was measured 3 mm behind the optic disc [16], and the measurement was taken between the outer edge of the hyperechoic optic nerve sheath (fig 1).

Fig 1. Measurement of optic nerve sheath diameter.
SWE measurements include the nasal and temporal sides of the peripapillary sclera, optic nerve head and the bulbar segment of the optic nerve (fig 2). The size of circular regions of interest (ROI) was fixed to 3 mm in all measurements. The mean Young’s modulus ‘Emean’ (kPa) within each ROI were recorded. The peripapillary sclera stiffness value was calculated as the average of the peripapillary sclera’s nasal and temporal sides. The average values of three measurements were used for statistical analysis.

Statistical analysis

The normality of the distribution was assessed using the Kolmogorov-Smirnov test. Continuous variables were expressed as a mean ± standard deviation. The independent samples T test, chi-square test and one-way ANOVA with a post hoc Bonferroni test were used for statistical analyses with SPSS version 23 software (SPSS Inc., Chicago, IL, United States). A p-value < 0.05 was considered statistically significant.

Results

This study included 54 healthy subjects and 54 patients with increased ICP. The aetiologies of increased ICPs were SOLs in 29 patients (53.7%) and ICH in 25 patients (46.3%). The SOLs group comprised 17 males (58.62%) with a mean age of 47.93±10.96 years and a mean ICP value of 23.90±4.77mmHg. The ICH group comprised 11 males (44%) with a mean age of 49.12±13.93 years and a mean ICP value of 24.12±3.79 mmHg. The control group comprised 30 males (55.56%) with a mean age of 46.94±14.16 years. There were no significant differences between the three groups in terms of age (ANOVA, p>0.05) or gender (chi-square test, p>0.05). The mean ICP values between the SOLs group and ICH group were similar (independent samples t-test, p>0.05).

The patients with increased ICP (the SOLs and ICH groups) had a similar optic nerve sheath diameter, Young’s modulus of optic nerve head and Young’s modulus of the peripapillary sclera (p>0.05, for all). The control group had a significantly lower optic nerve sheath diameter, Young’s modulus of optic nerve head and Young’s modulus of the peripapillary sclera than the increased ICP groups (p<0.01 for all). Young’s modulus of the optic nerve in the ICH group was similar to the control group, whereas the SOLs group had a significantly higher Young’s modulus of the optic nerve than the control group (p<0.05) (Table I).

In figure 3, we illustrated a SWE example from each SOLs group, ICH group, and control group.

Discussion

The posterior eye is the most common site for pressure-related ocular diseases. In this study, SWE was applied to evaluate the biomechanical properties of the posterior eye in healthy subjects and increased ICP patients, including SOLs and ICH patients. The results demonstrated that the optic nerve head and peripapillary sclera in patients with increased ICP were stiffer than healthy subjects. Moreover, SOLs patients had higher optic nerve stiffness than other subjects.

Tissue elasticity can be an indicator of its physiological and pathological characteristics. Recent studies have applied elastography techniques to ocular tissues [18-20] and suggested that these techniques could be safely used on the human eye. There is increasing evidence that the increased ICP is involved in the visual impairment in different kinds of eye conditions [12,21,22]. However, elastography studies about the influence of increased ICP on the posterior eye are very limited. To date, only one published report conducted by Zhou et al [23] evaluated posterior sclera elasticity in idiopathic intracranial hypertension patients by applying ultrasound vibro-elastography. They found a higher wave speed of posterior sclera in idiopathic intracranial hypertension patients as compared to healthy subjects. To our knowledge, there have been no studies that investigate the biomechanical properties of optic nerve head and optic nerve using SWE in patients with increased ICP. To get a full understanding of biomechanical properties of the posterior eye under increased ICP, we enrolled patients with two different causes of increased ICP, including SOLs and ICH. Furthermore, we evaluated the biomechanical properties of the optic nerve head, peripapillary sclera and the optic nerve by obtaining elasticity values using SWE.

At the optic disc, the retinal ganglion cell axons converge and pass through the lamina cribrosa to form the optic nerve. The lamina cribrosa is a mesh-like connective tissue within the optic nerve head, providing structural support to the nerve fibres and blood vessels [10]. The surrounding tissues of the optic nerve head are in direct contact with the sclera [24]. The optic nerve head and peripapillary sclera are the main load-bearing areas of the globe [25]. The optic nerve is surrounded by the optic nerve sheath, which is contiguous with the meninges of the brain. Optic nerve head and the peripapillary sclera separate the intraocular space and the intracranial subarachnoid space and form a barrier between these two pressure compartments [10].

Fig 3. Shear wave elastography measurements of the posterior eye a) in a 32-year-old male with meningioma (ICP value: 29 mmHg), showing a mean peripapillary sclera of 90.74 kPa, optic nerve head 30.79 kPa, optic nerve 17.51 kPa; b) in a 58-year-old male with intracranial haemorrhage (ICP value: 25 mmHg), showing a mean peripapillary sclera of 95.50 kPa, optic nerve head 24.10 kPa, optic nerve 11.46 kPa; c) in a 46-year-old healthy male, showing a mean peripapillary sclera of 71.08 kPa, optic nerve head 12.37 kPa, optic nerve 10.58 kPa.

Wang et al [11] imaged the lamina cribrosa using optical coherence tomography at various intraocular pressure and ICP combinations in a monkey model and found that the lamina cribrosa deformed in response to both intraocular pressure and intracranial pressure changes. Dikici et al [18] applied SWE and found glaucoma patients with high intraocular pressure have higher optic nerve head stiffness value than healthy subjects. We found that the stiffness values of the optic nerve head in patients with increased ICP were significantly higher than healthy subjects. The possible reason for this result is that increased cerebrospinal fluid pressure disturbs the retrolaminar pressure and results in stress build-up at the optic nerve head. The optic nerve sheath’s subarachnoid space is at the lower end of the cerebrospinal fluid system [26]. Increased ICP transmits to the optic nerve subarachnoidal space, causing expansion of the optic nerve sheath [27] and increased pressure in the optic nerve sheath subarachnoid [2]. The retrolaminar pressure is principally determined by the optic nerve sheath subarachnoid pressure [28]. Since the lamina cribrosa is the weak spot in the corneoscleral shell, increased retrolaminar pressure may increase stress and strain concentrations in this spot. Compression and distortion of the lamina cribrosa have direct effects of optic nerve head pathological changes [29]. According to previous studies, both acute [11] and chronic [22] elevation in ICP can lead to significant strain distribution changes within the optic nerve head.

We also found that peripapillary sclera in patients with increased ICP was significantly stiffer than healthy
the retina. Querfurth et al [31] found reduced flow velocities of the central retinal artery passes through the lamina cribrosa and feeds the optic nerve and inner two-thirds of the optic nerve head can block the axoplasmic flow and eventually lead to the loss of retinal ganglion cells [25]. Increased pressure-induced deformation of the lamina cribrosa directly squeezes nerve fibres and triggers neural tissue damage. These microstructural changes within the enclosed cavity leads to chronic increased ICP. Chronic exposure to a certain amount of biomechanical insult and ischemic hypoxic injury would likely trigger nerve cell degeneration and induce neural tissue remodelling [13] in the optic nerve, consistent with the high incidence of optic nerve atrophy in SOLs patients [32]. Optic nerve remodelling accompanied by fibrosis and atrophy changes its biomechanical properties and results in increased stiffness.

However, the ICH cause is bleeding from the ruptured blood vessel due to hypertension, abnormal, or trauma. The morbidity of ICH is generally related to the acute increased of ICP. Since the optic nerve sheath has a certain degree of elasticity [25], when the ICP increases acutely, the bulbar segment of the optic nerve sheath mark expands and alleviates some of the stress on the optic nerve, which may not be enough to cause neural tissue remodelling and stiffness change. The difference in Young’s modulus of the optic nerve between groups suggested that ICP may not be the only factor which influence the optic nerve stiffness. The difference in acute and chronic increased ICP may also account for the stiffness difference between groups.

There were several limitations to our study. Firstly, this study had a limited sample size; further studies with a larger sample size and longer-term follow-up assessment should be conducted. Secondly, tissue motion caused by subjects’ respiration and eye movement or probe movement can affect the elasticity results. Therefore, image quality evaluation was applied, which helps minimize motion interference and ensure the SWE examination’s accuracy and reproducibility. Besides, repeated measurements were obtained at least three times to reduce bias and errors.

In conclusion, we found that patients with increased ICP had a higher optic nerve head and peripapillary sclera stiffness than healthy subjects and SOLs patients had the highest optic nerve stiffness among all subjects. Elevation of ICP leads to elastic changes, firstly occurring in peripapillary structures; long-term exposure to increased pressure results in optic nerve fibrosis and increased stiffness. SWE could detect the posterior eye elasticity change in vivo and help the clinical practitioners estimate the degree of visual impairments.
