Abstract

Background: The most straightforward method of ascertaining arterial PO2, PCO2, and other components of blood gas is to measure them directly from a blood sample. In situations in which arterial puncture cannot be achieved or may be technically difficult, the venous blood sample can be used.

Methods: In a prospective analytical study, 80 patients undergoing mechanical ventilation after open-heart surgery in the intensive care unit were evaluated. Simultaneous, matched arterial and central venous blood gas samples were taken from radial artery line and central vein, respectively, when the ABG (arterial blood gases) assessment was needed. Arterial and central venous blood samples were analyzed and data were expressed as mean and ± SD.

Results: The Pearson correlation coefficient for pH, PCO2, HCO3, and SatO2 was 0.898, 0.940, 0.840, and 0.567, respectively. There was a significant correlation between arterial and central venous values of pH, PCO2, and HCO3 (P < 0.0001). The mean difference between arterial and central venous PCO2 was -2.44 ± 2.6 mmHg, and the mean venous pH value was only 0.021 ± 0.037 units lower than the mean arterial value. In addition, the calculated mean bicarbonate concentration in venous blood was only about 0.06 ± 1.5 mEq/L higher than the mean arterial value.

Conclusions: The central venous PCO2, pH, and HCO3 measured during mechanical ventilation in the intensive care unit approximate arterial values closely enough to permit the estimation of the adequacy of ventilation and acid-base status. The central venous Sat O2 does not reliably parallel the arterial Sat O2. In conclusion, venous blood sampling can potentially reduce the requirement for ABG sampling in special situations.

Keywords: Arteries, Central Venous, Blood Gas, Mechanical Ventilation, Surgery

1. Background

Arterial blood gas (ABG) analysis is used to assess oxygenation, ventilation, and acid-base status (1-3). ABG measurement is the most frequently ordered test in intensive care units. Therefore, taking an appropriate approach to this clinical test is important for the optimal care of the patients (4). The history of using and expanding arterial blood gases analysis is attributed to Severinghaus and Astrup (5, 6). Arterial blood gas analysis is a standard method for the assessment of oxygenation, ventilation, and the status of acids and bases in the body. The blood sample is usually taken through puncturing the arteries or through the implanted arterial catheter, which is accompanied by some complications such as hematoma, aneurysm formation, thrombosis, embolism, and the possibility of needle stick injury (7, 8).

When it is difficult or technically impossible, an alternative method is venous blood gas measurement. With both methods, we can obtain pH, oxygen pressure, carbon dioxide pressure, oxygen saturation, and the level of HCO3. Venous blood sampling is done easily while doing routine blood tests painlessly and without complications of arterial blood sampling. Various studies have been conducted regarding the relationship between arterial and venous blood values. Undoubtedly, determining the average of the difference in PCO2, HCO3, and pH of arterial and venous blood can be useful for managing the patients undergoing mechanical ventilation and for their weaning (9, 10).

A study in 2012 showed venous pH and HCO3 values had an excellent correlation with the values of arterial samples (11). On the other hand, a systematic review in 2014 showed that the peripheral venous and arterial PCO2 were not com-
parable (12).

We assume that the central venous blood has a close relationship with arterial blood. The purpose of this study was to examine this relationship in the patients who were candidates for open-heart surgery. In this study, data gathering did not impose any extra procedure because in patients under open-heart surgery, central venous and arterial catheter preparations are necessary for monitoring.

2. Methods

This study was conducted with the approval of the scientific and ethical review boards of Urmia University of Medical Sciences. 80 patients, who were admitted to the intensive care unit after cardiac surgery, were enrolled in our prospective analytic study. All patients were ASA (American society of anesthesiologists) physical status II - III according to the ASA’s classification system. Patients with ASA IV or more, with fever, with unstable hemodynamics, pneumothorax, hemothorax, respiratory, and heart failure were excluded from the study. In all patients, to check blood gases, samples were taken from arterial and central venous lines that were prepared in the operation room. Arterial samples were taken with 2 cc syringes, containing 0.1 cc heparin as an anticoagulant. First, air bubbles were removed and then were analyzed in 5 minutes. Simultaneously, central venous blood samples were taken and analyzed by using Nova biomedical model phox plus. All gathered data were statistically analyzed via chi-square and independent t-tests, or Fisher’s exact and Mann-Whitney U tests where needed by using SPSS version 20 software (Chicago, IL).

3. Results

In this prospective analytic study, 80 ASA II - III patients, who were transferred to the cardiac ICU to receive mechanical ventilation, were enrolled. Their arterial and central venous blood samples were analyzed. The mean age was 62.18 ± 11.57 years; 56 (70%) patients were male and 24 (30%) were female. The mean arterial and central venous blood pH values were 7.38 ± 0.03 and 7.36 ± 0.08, respectively, that were significantly correlated with each other (P = 0.0001 and R = 0.898). The mean difference between central venous and arterial pH was 0.007 ± 0.037 and 95% CI (Confidence Interval) regarding the difference in pH was 0.003 to 0.029. This indicates that the arterial pH was about 0.003 to 0.029 unit higher than the central venous pH (Figure 1 and Table 1).

Mean arterial and central venous PCO_2 were 36.3 ± 8.7 mmHg and 39.8 ± 8.9 mmHg, respectively, which were significantly correlated with each other (P = 0.0001, R = 0.954). The mean difference between arterial and central venous PCO_2 was -2.44 ± 2.6 mmHg and 95% CI regarding PCO_2 difference was 1.84 to 3.03 mmHg. Thus, arterial PCO_2 was approximately 1.84 to 3.03 mmHg less than the central venous PCO_2 (Figure 2 and Table 1).

Mean arterial and venous HCO_3 was 22.1 ± 2.8 and 22.1 ± 2.4 mEq per liter, respectively. Arterial and central venous HCO_3 were significantly correlated with each other (P = 0.0001, R = 0.840). The mean difference between arterial and central venous HCO_3 was -0.06 ± 1.5 mEq per liter and...
Table 1. Values of Arterial and Venous Blood Data\textsuperscript{a}

| Analysis | Arterial Blood | Venous Blood | Difference | CI 95% | R       |
|----------|----------------|--------------|------------|--------|---------|
| pH       | 7.38 ± 0.8     | 7.36 ± 0.08  | 0.021 ± 0.037 | 0.29 to 0.013 | 0.898   |
| PCO\textsubscript{2}, mmHg | 36.3 ± 8.7 | 39.8 ± 8.9 | -2.44 ± 2.6 | 1.84 to 3.03 | 0.940   |
| HCO\textsubscript{3}, mEq/L | 22.1 ± 2.8 | 22.1 ± 2.4 | -0.06 ± 1.5 | -0.4 to 0.2 | 0.840   |
| Sao\textsubscript{2}, % | 95.9 ± 4.7 | 89.4 ± 9.3 | 6.55 ± 7.76 | 4.8 to 8.2 | 0.567   |

\textsuperscript{a}Values are expressed as mean ± SD.

95% CI was -0.4 to 0.2 mEq/L in this regard (Figure 3 and Table 1).

Figure 3. The correlation between arterial and central venous blood HCO\textsubscript{3}. Pearson correlation coefficient shows the intensity of correlation. If the correlation was perfect (-1 or 1), in this case, all of the circles would be on a straight line.

When FiO\textsubscript{2} was approximately 50%, the mean arterial and central venous blood oxygen saturation (Scvo\textsubscript{2}) were 95.9 ± 4.7 and 89.4 ± 9.3, respectively. In this regard, the relationship between these amounts was very poor (R = 0.567) (Table 1).

4. Discussion

ABG analysis is a standard method for determining acid and basis status and adjusting mechanical ventilation based on oxygen pressure, arterial blood carbon dioxide, and pH. Arterial blood sampling as previously mentioned may be followed by some complications and even may lead to contaminated needles in the hands of staff and those who care patients during blood sampling (1, 7, 8). Patients who were candidates for open-heart surgery had a central venous line and an arterial line. Our goal was to study the relationship between pH, PO\textsubscript{2}, PCO\textsubscript{2}, and HCO\textsubscript{3} between central venous and arterial blood in these patients. We hope if desired results are achieved, central venous blood sampling will be used instead of arterial blood sampling for arterial blood gas analysis. In this study, arterial and central venous blood samples were correlated regarding PCO\textsubscript{2}, pH, and HCO\textsubscript{3} and 95% Confidence Intervals were very close and could be easily used in the results of ABG and central VBG.

In 1961, Gombino compared capillary blood and brachial arterial blood of patients who had referred for pulmonary tests and reported that there was no significant difference between them (13). Kim et al. in 2012 in Korea determined peripheral venous and arterial blood gas correlation in ICU patients and reported that peripheral venous pH, PCO\textsubscript{2}, and HCO\textsubscript{3} may be used as alternatives to their arterial equivalents in many clinical contexts encountered in the ICU (14). Our study results do not correlate with their studies. The difference of our study is that the blood sample was taken from the central vein and, as their studies showed, they could be taken from the central VBG in cases where ABG is not available. Nevertheless, we had a weak correlation between the mean oxygen saturation of the arterial and central venous blood.

The monitoring of the mixed venous oxygen saturation (SMVO\textsubscript{2}) has been used for delivery and consumption of oxygen in critically ill patients. Most critically ill patients have a central venous catheter and the central venous oxygen saturation (SCVO\textsubscript{2}) has been used as an alternative to the SMVO\textsubscript{2}. A few studies were conducted for hemodynamic monitoring with SCVO\textsubscript{2}, but their results in various situations were different (2, 15, 16). Based on these data, the surviving sepsis campaign has recommended achieving a SMVO\textsubscript{2} level of 65% or a SCVO\textsubscript{2} level of 70% in septic shock patients.

Various studies have been done to evaluate patients under different conditions. For example, Kelly et al. (17) studied the correlation between arterial and venous HCO\textsubscript{3} in patients in emergency wards who had respiratory or metabolic disorders and announced that measuring venous blood bicarbonate could be a good alternative for estimating arterial HCO\textsubscript{3}. On the other hand, the correlation between arterial and venous blood gases was studied in patients with acute exacerbations of chronic obstructive pulmonary disease (COPD), patients poisoned by tricyclic antidepressants, patients with acute respiratory failure un-
derned for estimating PVo2 of central venous blood gases, and their values can be estimated in different situations by adding or subtracting the amounts of central venous blood gases, and their values can be estimated in different situations by adding or subtracting the amounts. In the study of Yildizdas et al. (19), a similar correlation in this study was reported. The results of this study help us in the study of Yildizdas et al. (19), a similar correlation in this study was done after open-heart surgery.

In the present study, the correlation between arterial and central venous blood oxygen saturation was poor. In the study of Yildizdas et al. (19), a similar correlation in this study was reported. The results of this study help us in the study of Yildizdas et al. (19), a similar correlation in this study was done after open-heart surgery. Further study was done on these patients because both arterial and central venous lines are required for the process of anesthesia for cardiac surgery and no more procedures were imposed on patients. In addition, patients were not punctured for taking arterial and venous blood and thus, the results of this study can be used in similar cases. In this study, the correlation between Sat O2 of arterial and central venous blood (SVO2) was poor. Perhaps it could be better to use some devices such as pulse oximetry for the evaluation of these indices and regarding other blood gases, the analysis of venous blood gases can be applied. In conclusion, it seems that other similar studies can be done in patients who have hemodynamic instability or long-term hypotension or even in patients undergoing cardiopulmonary resuscitation in order to examine the correlation rate in this regard.
