Submitted to ApJ

ABSTRACT

The ionizing background determines the ionization balance and the thermodynamics of the cosmic gas. It is therefore a fundamental ingredient to theoretical and empirical studies of both the IGM and galaxy formation. We present here a new calculation of its spectrum that satisfies the empirical constraints we recently obtained by combining state-of-the-art luminosity functions and intergalactic opacity measurements.

In our preferred model, star-forming galaxies and quasars each contribute substantially to the HI ionizing field at \( z < 3 \), with galaxies rapidly overtaking quasars at higher redshifts as quasars become rarer. In addition to our fiducial model, we explore the physical dependences of the calculated background and clarify how recombination emission contributes to the ionization rates. We find that recombinations do not simply boost the ionization rates by the number of remitted ionizing photons as many of these rapidly redshift below the ionization edges and have a distribution of energies. A simple analytic model that captures the main effects seen in our numerical radiative transfer calculations is given.

Finally, we discuss the effects of HeII reionization by quasars on both the spectrum of the ionizing background and on the thermal history of the IGM. In regions that have yet to be reionized, the spectrum is expected to be almost completely suppressed immediately above 54.4 eV while a background of higher-energy (\( \gtrsim 0.5 \) keV) photons permeates the entire universe owing to the frequency-dependence of the photoionization cross section. We provide an analytical model of the heat input during HeII reionization and its effects on the temperature-density relation.

Subject headings: Cosmology: theory, diffuse radiation — galaxies: formation, evolution, high-redshift — quasars: absorption lines

1. INTRODUCTION

The cosmic baryons give the ultraviolet (UV) background a particularly important standing among radiation backgrounds. In fact, the ionization potentials of both hydrogen and helium\(^3\), which together account for 99% of the baryonic mass density (e.g., Burles et al. 2001), correspond to electromagnetic wavelengths in the UV regime. The UV background therefore governs the ionization state of intergalactic gas and furthermore plays a key role in its thermal evolution through photoheating. As such, it is an essential input to cosmological hydrodynamic simulations (e.g., Hernquist et al. 1996; Katz et al. 1996; Davé et al. 1999; Springel & Hernquist 2003) as well as to observational studies of the intergalactic medium (IGM).

The ionizing background can for example suppress the abundance of dwarf galaxies and the amount of cool gas in low-mass galaxies that do form both by modifying the cooling function through the ionization balance and by heating the gas before it collapses. It is also crucially important for any simulation of the Ly\( \alpha \) forest, since the absence of a Gunn & Peterson (1965) trough in the spectra of quasars up to \( z \sim 6 \) (e.g., Fan et al. 2002, 2006; Becker et al. 2007) indicates that the IGM is highly ionized up to at least that redshift. Since the optical depth of the Ly\( \alpha \) forest is directly tied to the hydrogen photoionization rate (e.g., Rauch et al. 1997; McDonald & Miralda-Escudé 2001; Meiksin & White 2003; Tytler et al. 2004; Kirkman et al. 2005; Bolton et al. 2006; Faucher-Giguère et al. 2008), it is important to know the latter accurately. In addition, the UV background determines the photoionization rate of helium, which is of particular relevance given the growing interest in studying HeII reionization, which may occur at redshifts \( z \sim 3 - 4 \) for which a wealth of observational data are already available and upcoming. It is also expected to be completely suppressed above 54.4 eV. The full spectrum of the UV background is perhaps most important in the study of metal ions, such as SIV and CIV, where relating the ionic abundances to elemental abundances or cosmic metal mass density requires ionizing corrections (e.g., Cowie et al. 1995; Songaila & Cowie 1996; Songaila et al. 2001; Schaye et al. 2003; Boksenberg et al. 2003; Aguirre et al. 2004; Simcoe et al. 2004; Fechner & Richter 2008). Finally, the spectrum of the UV background obviously depends on its sources and its study can therefore teach much about the sources responsible for keeping the IGM ionized, as well as reionizing it (e.g., Miralda-Escudé 2003; Bolton & Haehnelt 2007; Faucher-Giguère et al. 2008).

We review the basic equations of cosmological radiative transfer and the column density distribution of HI ab-

and provide a physical framework to implement them.

discuss the effects of HeII reionization on the UV background spectrum as well as on the thermal history of the IGM.

The effects of HeII dependences on input parameters are presented in §5. In this work, we are first concerned with the specific intensity of the diffuse cosmological UV background averaged over

and the corresponding ionization rates depend on input parameters. The effects of HeII reionization are investigated in §7. We finally compare our results with previous work in §8 and conclude in §9.

Throughout, we assume a cosmology with \((\Omega_m, \Omega_b, \Omega_{\Lambda}, \, h, \, \sigma_8) = (0.28, 0.046, 0.72, 0.70, 0.82)\), as inferred from the Wilkinson Microwave Anisotropy Probe (WMAP) five-year data in combination with baryon acoustic oscillations and supernova (Komatsu et al. 2008). Unless otherwise stated, all error bars are 1σ. Table I defines many symbols used here.

2. COSMOLOGICAL RADIATIVE TRANSFER

2.1. Radiative Transfer Equations

In this work, we are first concerned with the specific intensity of the diffuse cosmological UV background averaged over both space and angle, which we denote by \(J_\nu\). The basic equations of cosmological radiative transfer were particularly well summarized by Haardt & Madau (1996), on which we base our treatment below. The specific intensity satisfies the radiative transfer equation,

\[
\left( \frac{\partial}{\partial t} - \nu H \frac{\partial}{\partial \nu} \right) J_\nu = -3HJ_\nu - c\alpha_\nu J_\nu + \frac{c}{4\pi} \epsilon_\nu, \tag{1}
\]

where \(H(t)\) is the Hubble parameter, \(c\) is the speed of light, \(\alpha_\nu\) is the proper absorption coefficient, and \(\epsilon_\nu\) is the proper emissivity. Integrating equation (1) and expressing the result in terms of redshift gives

\[
J_{\nu_0}(z_0) = \frac{1}{4\pi} \int_{\nu_0}^{\infty} d\nu \frac{d\nu}{dz} \frac{(1 + z_0)^3}{(1 + z)^3} \epsilon_\nu(z) \exp[-\tau(\nu_0, z_0, z)], \tag{2}
\]

where \(\nu = \nu_0(1 + z)/(1 + z_0)\), the proper line element \(d\nu/dz = c/[1 + z]H(z)\), and the “effective optical depth” \(\tau^4\) quantifies the attenuation of photons of frequency \(\nu_0\) at redshift \(z_0\) that were emitted at redshift \(z\) by the relation

\[
\tau(z) = \int_0^z \frac{d\tau}{dz} \, dz.
\]

This quantity is often denoted by \(\tau_{\text{eff}}\). We use a different notation here to distinguish it from the effective optical depth \(\tau_{\text{eff}}(z) = -\ln \langle F(z) \rangle\) owing to Ly\(\alpha\) absorption measured from quasar spectra (e.g., Faucher-Giguère et al. 2008d).
\[ e^\bar{\tau} = \langle e^{-\tau} \rangle, \] where the average is over all lines of sights from \( z_0 \) to \( z \). For Poisson-distributed absorbers, each of column density \( N_{\text{HI}} \),

\[
\bar{\tau}(\nu_0, z_0, z) = \int_{z_0}^{z} dz' \int_{0}^{\infty} dN_{\text{HI}} \frac{\partial^2 N}{\partial N_{\text{HI}} \partial z'} (1 - e^{-\tau}),
\]

where \( \partial^2 N / \partial N_{\text{HI}} \partial z' \) is the column density distribution versus redshift \cite{Paresce1980}.

Note that these expressions neglect the clustering of sources and sinks of radiation in both the Poisson distribution assumption and in assuming that the spatial average \( \langle \tau(\nu_0, z_0, z) \rangle \) separates into \( \langle \tau(\nu_0, z_0, z) \rangle \). The Poisson distribution assumption should be very good since the mean free path of ionizing photons of hundreds of comoving Mpc at most redshifts of interest (see \cite{Paresce1980}) far exceeds the correlation length \( \lesssim 5 \) comoving Mpc of the Ly\( \alpha \) forest absorbers \cite{McDonald2000, Faucher-Giguere2008c}. While absorbers likely do cluster around sources, this effect can be viewed as being incorporated into the definition of the escape fraction. The above formalism will however break down in certain regimes where sources are rare and in particular during He\( \text{II} \) reionization. We discuss these cases in \cite{Faucher-Giguere2008c}. As in equation 2 we henceforth drop the explicit averaging brackets around the emissivity \( \epsilon_\nu \).

The optical depth \( \tau_\nu \) shortward of the Lyman limit will be dominated by the photoelectric opacity of hydrogen and helium,

\[
\tau_\nu = N_{\text{HI}} \sigma_{\text{HI}}(\nu) + N_{\text{HeI}} \sigma_{\text{HeI}}(\nu) + N_{\text{HeII}} \sigma_{\text{HeII}}(\nu),
\]

where the \( N_i \) and \( \sigma_i \) are the column densities and photoionization cross sections of ion \( i \). Only the distribution of \( N_{\text{HI}} \) is reasonably well determined over a large redshift interval. We will therefore make use of relations between \( N_{\text{HI}} \) and the column densities of helium established in \cite{Paresce1980}. In our calculations, we will prescribe \( \partial^2 N / \partial N_{\text{HI}} \partial z \) as well as the specific emissivity of the ionizing sources, \( \epsilon_\nu^\text{arc} \), based on our previous empirical studies \cite{Faucher-Giguere2008c}.

### 2.2. \( \text{HI} \) Column Density Distribution

Following previous work and consistent with empirical constraints, we parameterize the column density distribution with power laws in \( N_{\text{HI}} \) and \( z \):

\[
\frac{\partial^2 N}{\partial z \partial N_{\text{HI}}} = \begin{cases} 
N_{0,\text{low}} N_{\text{HI}}^{-\beta} (1 + z)^{\gamma_{\text{low}}} & z \leq z_{\text{low}} \\
N_{0} N_{\text{HI}}^{-\beta} (1 + z)^{\gamma} & z > z_{\text{low}}.
\end{cases}
\]

The transition at \( z_{\text{low}} \) accounts for the flattening of the redshift evolution observed at \( z \lesssim 1.5 \) \cite{Weymann1998, Kim2001, Kim2002} theoretically understood to arise from the drop in intensity of the ionizing background at low redshifts \cite{Theuns1998, Davé1999, Bianchi2001, Scott2002}. We fix \( \gamma_{\text{low}} = 0.2 \).

For a steep column density distribution with \( \beta < 2 \), most of the contribution to \( \bar{\tau} \) at the Lyman limit arises from systems of optical depth near unity \( (N_{\text{HI}} \approx 10^{17.2} \text{ cm}^{-2}) \). We thus focus on the values of the power-law indices \( \beta \) and \( \gamma \) that are most appropriate in this neighborhood. \cite{Stengler-Larrea1995} find that \( dN_{\text{HI}}/dz = C (1 + z)^{\gamma} \) with \( C = 0.25 \) and \( \gamma = 1.5 \) provides a good fit at least up to \( z = 4.1 \) for systems with \( N_{\text{HI}} \gtrsim 10^{17.2} \text{ cm}^{-2} \), whereas
the column density power law is well-fitted by $\beta = 1.4$ (Misawa et al. 2007). The constant $N_0$ in equation 5 is related to $C$ by $N_0 = (\beta - 1)CN_{\text{HI},\text{min}}^{\beta-1}$, where $N_{\text{HI},\text{min}} = \sigma_{\text{HI}}^{-1} = 10^{17.2}$ cm$^{-2}$. We use these values, with $z_{\text{low}} = 1.5$, in fiducial calculations but explore varying these parameters in §6.

Before proceeding, we note that column density distribution is largely unconstrained above $z = 4.1$, the highest redshift at which the Lyman limit system abundance has been measured. We therefore simply extrapolate from lower redshifts and caution that our calculation of the ionizing background may become inaccurate in this regime. In particular, we expect the extrapolation to become unreliable at $z \approx 5.7$, where the evolution of the effective optical depth measured from the spectra of $z \geq 6$ quasars diverges rapidly from the power law fitting the data below this redshift (Fan et al. 2006b), though see Becker et al. (2007) for an opposing point of view, perhaps owing to HI reionization.

3. THE IONIZATION STRUCTURE OF INDIVIDUAL ABSORBERS

3.1. Overview

In this section, we study the photoionization equilibrium structure of individual cosmic absorbers composed of hydrogen and helium (with mass fraction 75% and 25%, respectively) as a function of the illuminating radiation background. This serves two purposes: close the set of equations of cosmological radiative transfer ($\S$2) and allow us to more realistically calculate the contribution of recombination lines to the ionizing background spectrum ($\S$4). To this end, we have developed a code that self-consistently solves the photoionization equilibrium balance, including the influence of recombination radiation. This code provides more accurate solutions than previous approximations with semi-infinite geometry and an escape probability formalism (Haardt & Madau 1996) or gray cross sections (Fardal et al. 1998). To alleviate the text, the details of our photoionization calculations are provided in Appendix A. We assume our absorbers to be sheets infinite in extent but of thickness equal to the Jeans scale of the gas, which is a function of the assumed temperature $T = 2 \times 10^4$ K (Schaye 2001).

3.2. $N_{\text{HeII}}$ and $N_{\text{HeI}}$ from $N_{\text{HI}}$

As only the column density distribution of HI is reasonably well constrained, the first application of our photoionization calculations is to obtain relations giving $N_{\text{HeII}}$ and $N_{\text{HeI}}$ in terms of $N_{\text{HI}}$. In Figure 1, we show the numerical results for external spectra $J_\nu = 10^{-21}$ erg s$^{-1}$ cm$^{-2}$ Hz$^{-1}$ sr$^{-1}(\nu/\nu_{\text{HI}})^{-\alpha}$ with $\alpha = 0.0, 0.5, 1.0, 1.5, 2.0$, and 2.5 from bottom up. To ensure that these test spectra are representative of the UV background, we suppress the power laws by a factor of 10 above the HeII ionization edge.

Since these relations enter within three nested integrals (eqs. 1 and 2), it is necessary to develop analytical approximations that are fast to evaluate. Defining $\eta \equiv N_{\text{HeII}}/N_{\text{HI}}$, when both HI and HeII are optically thin and in the limit of nearly complete ionization we have

$$\eta_{\text{thin}} = \frac{I_{\text{HI}}}{16X Y / \Gamma_{\text{HeI}}} N_{\text{HeII}} = \frac{I_{\text{HeII}}}{1 + B \tau_{\text{HeII}}} I_{\text{HeII}}.$$

For fixed external background and increasing $N_{\text{HI}}$, an absorber first becomes optically thick in HeII, at which point $\eta$ increases rapidly with $N_{\text{HI}}$. The absorber then becomes optically thick in HI as well and, owing to the greater abundance of hydrogen, $N_{\text{HI}}$ finally rapidly overtakes $N_{\text{HeII}}$. This leads to the plateau, increase, and then decrease of $\eta$ with respect to $N_{\text{HI}}$ seen in the numerical calculations.

Fardal et al. (1998) give a fitting formula derived under the assumptions of negligible $N_{\text{HeI}}$ and $n_{\text{HeII}}/n_{\text{H}} \ll 1$:

$$Y \frac{\Gamma_{\text{HeI}}}{16X} \frac{\tau_{\text{HI}}}{1 + B \tau_{\text{HeII}}} I_{\text{HI}} = \eta_{\text{HeII}} = \eta_{\text{HeII}} = \frac{\tau_{\text{HeII}}}{1 + B \tau_{\text{HeII}}} I_{\text{HeII}}.$$

where $I_\xi = \Gamma_{\text{ext}}/n_e \sigma_{\text{H}}$, $\tau_{\text{HI}} = \sigma_{\text{HI}} N_{\text{HI}}$ and $\tau_{\text{HeII}} = \sigma_{\text{HeII}} N_{\text{HeII}}$, and we have generalized their result to allow for arbitrary coefficients $A$ and $B$. These fitting coefficients depends on, in particular, the relation between $N_{\text{HI}}$ and $n_e$ and we will not be using the same model as these authors. Although our numerical calculations do not a priori assume a relation between $N_{\text{HI}}$ and $n_e$, we must assume one in order to make use of the analytic approximation in equation 3. The approximation curves in Figure 1 can be reproduced by taking $n_e = 1.4 \times 10^{-3}$ cm$^{-3}$ ($N_{\text{HI}}/10^{17.2}$ cm$^{-2}$)$^{2/3} (\Gamma_{\text{HI}}/10^{-12}$ s$^{-1})^{2/3}$. This relation is approximately derived under the assumption of Jeans length thickness of the absorbers and optically thin photoionization equilibrium at $T = 2 \times 10^4$ K. Figure 1 shows that $A = 0.15$ and $B = 0.2$ give a good fit to our numerical results for a wide range of external illuminating spectra. The fitting formula has the exact optically thin limit; the asymptotic divergence from the numerical results as $N_{\text{HI}} \rightarrow \infty$ is unimportant as most of the HeII opacity arises in systems with $\tau_{\text{HI}} \lesssim 1$.

Obtaining a physically-motivated analytic approximation to $\zeta \equiv N_{\text{HeII}}/N_{\text{HI}}$ is more difficult since $y_{\text{HeII}}$ is not readily known (for $\eta$, we know that $\tau_{\text{HI}} \approx 1$ in the almost-completely ionized case, so that the ionized fractions do not appear explicitly in eqs 6 and 7). Because the ionization potential of HeI is relatively close to that of HI, their ionization states are similar and since helium is less abundant by a factor of 12 by number, HeI should contribute
relatively little to the ionizing opacity. This intuition is supported by the right panel of Figure 14, which shows that $\zeta$ versus $N_{\text{HI}}$ is $\ll 1$ for illuminating spectra considered. After hardening by IGM filtering, both star-forming galaxies and quasars are expected to produce roughly flat spectra between the HI and HeI ionization edges (§5), so that a representative case is $\alpha \approx 0$, yielding $\zeta \lesssim 10^{-3}$. We therefore approximate $\zeta = 0$ in our cosmological calculations and verify using toy cases of constant $\zeta$ that this is justified in §6.

Fig. 1.— Ratio $\eta = N_{\text{HeII}}/N_{\text{HI}}$ (left) and $\zeta = N_{\text{HeI}}/N_{\text{HI}}$ (right) as a function of HI column density. The solid curves show full numerical photoionization calculations and the dashed ones show analytical approximations based on equation 7 for $\eta$. From the bottom up, power-law external spectra $J_\nu = 10^{-21}$ erg s$^{-1}$ cm$^{-2}$ Hz$^{-1}$ sr$^{-1}(\nu/\nu_{\text{HI}})^{-\alpha}$ with $\alpha = 0.0$, 0.5, 1.0, 1.5, 2.0, and 2.5, suppressed by a factor of 10 above the HeII ionization edge, are assumed.

4. RECOMBINATION EMISSION

4.1. Cosmological Emissivity

The cosmic absorbers not only act as sinks but also as sources of ionizing radiation as a certain fraction of ionizations are followed by the reemission of other ionizing photons via recombinations (Fardal & Shull 1993; Haardt & Madau 1996; Fardal et al. 1998). This recombination emission must be taken into account because it may boost the photoionization rates and also since line reemission can imprint significant narrow features in the ionizing background spectrum. Our approach to include this recombination contribution is based on the self-consistent numerical calculations of recombination emission from individual absorbers using the code outlined in the previous section and detailed in Appendix A. This again differs from Haardt & Madau (1996), who used an analytical escape probability formalism and made the assumption of a constant source function within the absorbers (which breaks down in the very optically thick systems), and from the treatment of Fardal et al. (1998) and thus provides a check of these results.

For each recombination process of interest, we calculate the emergent specific intensity $I_{\nu}^{\text{rec}}(N_{\text{HI}})$ owing to the process given the external illuminating spectrum numerically using our photoionization code. The cosmological recombination emissivity for this process is then an average over the column density distribution:

$$I_{\nu}^{\text{rec}} = 4\pi \frac{dz}{dl} \int_0^\infty dN_{\text{HI}} \frac{d^2N}{dz dN_{\text{HI}}} I_{\nu}^{\text{rec}}(N_{\text{HI}}).$$

(8)

Since in general $I_{\nu}^{\text{rec}}(N_{\text{HI}})$ depends on the spectrum of the ionizing background, which is not known a priori and evolves at each step in the redshift integration, it is again necessary to obtain an analytical approximation for this function that scales appropriately with the external background. We develop these analytical approximations in Appendix B for each recombination process of interest.

4.2. Recombination Processes

For hydrogen, the only ionizing process is direct recombination to the ground state, which produces a 1 Ryd HI LyC photon. For helium, both recombinations to HeII and to HeI can in principle produce ionizing photons. In cosmological conditions, HeI plays a negligible role (§3.2 and 6; Haardt & Madau 1996) and we will ignore it in our reemission calculations. Three permitted HeII recombination channels lead to the reemission of ionizing photons: HeII LyC recombinations directly to the ground state, indirect recombinations leading to HeII Ly$\alpha$ emission, and recombinations to the $n = 2$ excited level resulting in Balmer continuum (BalC) photons. These respectively give
\[ N_{\text{HI}} (\text{cm}^{-2}) \]

\[ \Gamma_{\text{rec}} / \Gamma_{\text{ext}} \]

\( \alpha = 1.0 \) \hspace{1cm} \( \alpha = 1.5 \) \hspace{1cm} \( \alpha = 2.0 \) \hspace{1cm} \( \alpha = 2.5 \)

\[ \int d\nu J_{\nu, HI \text{ LyC}} \left( 10^{-9} \text{ erg s}^{-1} \text{ cm}^{-2} \text{ sr}^{-1} \right) \]

\[ J_{\infty}^{\nu} = 10^{-21} \text{ erg s}^{-1} \text{ cm}^{-2} \text{ Hz}^{-1} \text{ sr}^{-1} \left( \nu / \nu_{\text{HI}} \right)^{-\alpha} \]

\[ \alpha = 0.0, 0.5, 1.0, 1.5, 2.0, \text{ and } 2.5, \text{ suppressed by a factor of } 10 \text{ above the HeII ionization edge, are assumed.} \]

Fig. 2.— Ratio of the HI photoionization rate outside an individual absorber that is contributed by different recombination processes (HI LyC in blue, HeII BalC in red, HeII Ly\( \alpha \) in magenta, HeII LyC in green) to the external photoionization rate. The solid curves show full numerical integrations over photo-ionized slabs (eq. B2) and the dashed ones show analytical approximations based on the optically thin limit (eq. B3) and saturation in the optically thick regime described in §B.2. External power-law spectra \( J_{\infty}^{\nu} = 10^{-21} \text{ erg s}^{-1} \text{ cm}^{-2} \text{ Hz}^{-1} \text{ sr}^{-1} \left( \nu / \nu_{\text{HI}} \right)^{-\alpha} \) with \( \alpha = 1.0, 1.5, 2.0, \text{ and } 2.5, \text{ suppressed by a factor of } 10 \text{ above the HeII ionization edge, are assumed.} \)

Fig. 3.— Frequency integral of HI Ly\( \alpha \) reemission as function of HI column density. The solid curves show full numerical photoionization calculations and the dashed ones show analytical approximations based on equation B8. From the bottom up, power-law external spectra \( J_{\infty}^{\nu} = 10^{-21} \text{ erg s}^{-1} \text{ cm}^{-2} \text{ Hz}^{-1} \text{ sr}^{-1} \left( \nu / \nu_{\text{HI}} \right)^{-\alpha} \) with \( \alpha = 0.0, 0.5, 1.0, 1.5, 2.0, \text{ and } 2.5, \text{ suppressed by a factor of } 10 \text{ above the HeII ionization edge, are assumed.} \)

photons of energy 4, 3, and 1 Ryd. We do not include forbidden two-photon recombination processes as these are energetically subdominant and do not result in significant narrow emission features.

In calculating the contribution of reemission to the photoionization rates, it is important to model the finite width of the recombination lines. For example, if HI LyC reemission is incorrectly modeled as a \( \delta \)-function, the reemission photons are immediately redshifted below the HI ionization edge and are lost as contributors to the ionizing
For continuum recombinations, the line profile is well approximated by

$$
\phi_{\text{rec}}(\nu) = \frac{(\nu/\nu_{\text{rec}})^{-1} \exp(-h\nu/kT) \theta(\nu - \nu_{\text{rec}})}{\Gamma(0, h\nu_{\text{rec}}/kT)} \nu_{\text{rec}},
$$

where $T$ is the temperature of the gas and $\theta(\Delta \nu)$ is the Heaviside function which is 1 for $\Delta \nu \geq 0$ and 0 otherwise (Appendix E). Electrons in gas at higher temperature tend to have large kinetic energy and so give rise to higher-energy recombination photons that take longer to redshift below the ionization edge. For Ly$\alpha$ emission, either by HI or HeII, a $\delta-$function profile $\phi_{\text{HI/HeII Ly}\alpha}(\nu) = \delta(\nu - \nu_{\text{HI/HeII Ly}\alpha})$ is however appropriate because of the narrow intrinsic line width (much smaller than the mean free path by which photons are redshifted before being reabsorbed) and its distance from the ionization edges.

The analytical approximations for the recombination emission from individual absorbers are compared to the full numerical calculations in Figure 2 for the ionizing processes. In all cases, $\Gamma_{\text{HI}}^\text{rec}/\Gamma_{\text{HI}}^\text{tot}$ (where we define $\Gamma_{\text{HI}}^\text{tot}(N_{\text{HI}}) = 4\pi \int_\nu^\infty d\nu/(h\nu) \Gamma_{\nu}^\text{HI}(N_{\text{HI}}) \sigma_{\text{HI}}(\nu)$) is maximum for HI LyC reemission, as expected since hydrogen recombinations are more frequent owing to its greater abundance and these recombination photons have the largest photoionization cross section, and is equal to about 10%. The helium recombination processes all contribute at the $10^{-3}$ level or less. Note, however, that HeII LyC reemission will contribute more significantly to the HeII ionizing background and that processes which contribute negligibly to the photoionization rates can still imprint important narrow features in the background spectrum that can be important for metal line studies. The agreement between the numerical calculations and analytical approximations is generally good and the approximations scale well for different spectral indices. Discrepancies of a factor of a few exist over some column density intervals, particularly for the HeII BalC and HeII LyC processes. These processes are complex in their details that depend on the non-monotonic relative ionization of hydrogen and helium (Fig. 1) but their contributions are nevertheless reasonably well captured and fortunately subdominant to the photoionization rates. In contrast, the dominant contribution of reemission to the hydrogen ionizing background, HI LyC emission, involves only hydrogen and is accurately and robustly approximated.

Figure 3 compares the analytical approximation for HI Ly$\alpha$ approximation to the full numerical solutions. In this case, both the optically thin and optically thick limits are accurately captured, resulting in an excellent approximation at all column densities that scales correctly with the external illuminating spectrum.

### 5. Empirically Calibrated Spectra

#### 5.1. Quasar and Stellar Emissivities

Having established efficient approximations for the radiative transfer within individual absorbers (§3 and 4), we proceed to include these in the solution of the cosmological radiative transfer problem (§2). Our prescriptions for the sources of ionizing radiation are based on the empirical constraints obtained in Faucher-Giguère et al. (2008d,a,b). Note, however, that these prescriptions can easily be modified to accommodate further constraints: our numerical code can compute the ionizing background for arbitrary input emissivities. We explore variations about these fiducial parameters in §6. Here, we consider two dominant known sources of ionizing radiation: quasars and star-forming galaxies.

For the quasar emissivity, we use the quasar luminosity function of Hopkins et al. (2007) based on a large set of observed quasar luminosity functions in the infrared, optical, soft and hard X-rays, as well as emission line measurements. Denoting by $\epsilon_B$ the emissivity at 4400 Å and assuming $L_B \equiv \nu L\nu|_{4400}$ Å,

$$
\epsilon_{\nu,\text{QSO,com}} = \int_0^\infty dL_B \frac{d\phi_{\nu}}{dL_B} \frac{L_B}{\nu_{4400}},
$$

where $d\phi/dL_B$ is the $B$-band luminosity function in comoving units. The emissivity shortward of 4400 Å is calculated assuming that quasars have a spectral index $\alpha = 0.3$ at 2500–4400 Å, 0.8 at 1050–2500 Å (Madau et al. 1999), and $\alpha_{\text{QSO}}$ shortward of 1050 Å. In order to match the total HI photoionization rate measured from the Ly$\alpha$ forest and to account for uncertainties in converting from the emissivity at 4400 Å to the photoionization rate, we allow this emissivity to be normalized by a constant factor (see §2.2). In our fiducial model, $\alpha_{\text{QSO}} = 1.6$ (Telfer et al. 2002), but note that other studies have found both softer and harder spectra, with a significant variance about the mean (e.g., Zheng et al. 1997; Scott et al. 2004).

For the stellar emissivity, we assume that the emissivity is proportional to the star formation rate density,

$$
\epsilon_{\nu,\text{com}} = K \rho_{\star,\text{com}},
$$

with the observationally-calibrated proportionality constant accounting for the efficiency of conversion of mass into ionizing photons. We use the theoretical star formation history of Hernquist & Springel (2003) developed from a combination of hydrodynamical simulations (Springel & Hernquist 2003) and simple analytical arguments. In Faucher-Giguère et al. (2008b), we found that this model provides a better fit at high redshifts to the opacity of the Ly$\alpha$ forest.
over $z = 2 - 4.2$, is easier to reconcile with hydrogen reionization completing by $z = 6$, and is in better agreement with the rate of long gamma-ray bursts observed by Swift than many of the existing measurements based on galaxy surveys, among which there is still a wide dispersion. We use equation 45 of Hernquist & Springel (2003) to scale their fiducial model to the WMAP5 cosmology assumed in this work. We assume, motivated by the theoretical starburst calculations of Kewley et al. (2001), that star-forming galaxies have a spectral index $\alpha_\nu = 1$ between 1 and 4 Ryd. This model is applicable for the stellar populations calculated with the PEGASE code using the Clegg & Middlemass (1987) atmosphere models for Wolf-Rayet stars. While different theoretical assumptions lead to significant variance in the 1–4 Ryd spectrum, this model provides the best observational match to the hard starburst spectra inferred by optical line diagnostics by Kewley et al. (2001). We assume that they effectively emit no harder photons, the theoretical calculations showing a break of several orders of magnitude at the HeII ionization edge. In the UV spectrum redward of 1 Ryd, we take $\alpha_\nu = 0$, consistent with the LBGs observed by Shapley et al. (2003). Finally, we assume that the stellar emissivity has a discontinuity of a factor of 4 at the Lyman limit. While this factor is not well constrained, this is of roughly the magnitude predicted by spectral synthesis models (Leitherer et al. 1999; Bruzual & Charlot 2003).

The emissivities are converted to proper units before being inserted in the solution to the cosmological radiative transfer solution in equation (2) and the total emissivity is then $\epsilon_\nu(z) = \epsilon_{QSO}^\nu(z) + \epsilon_\nu^\nu(z) + \epsilon_{recomb}^\nu(z)$.

![Fig. 4.— Spectra of the UV background obtained by solving the cosmological radiative transfer equation (eq. 1) at different redshifts for our empirically-calibrated fiducial model with star-forming galaxies and quasars described in §3. The thin curves ignore recombination emission by intergalactic absorbers and the thicker curves include this contribution. Star-forming galaxies dominate the HI photoionization rate at $z \gtrsim 3$, with the quasar contribution becoming more important as the $z \sim 2$ peak of the quasar luminosity function is approached. Only quasars are assumed to produce HeII ionizing photons and only they contribute to HeII recombination processes. The integrated photoionization rates are given in Figure 5.](image)

5.2. Results

In Figure 4, we show the calculated cosmological UV background spectra at $z = 0 - 5$ for the fiducial model above, with and without the recombination processes included. Since only quasars are assumed to contribute photons above the 4 Ryd HeII ionization edge, only them contribute to the HeII recombination lines and photoionization rate.

In Figure 5, we show the integrated photoionization rates of HI and HeII, as well as the fractional contribution of recombination lines with respect to the total background including both stars and quasars. The quasar contribution to the HI ionizing background increases toward $z \sim 2$ as the peak of the quasar luminosity function is approached; the $z \gtrsim 3$ photoionization rate is dominated by stellar emission. The fractional recombination contribution to the HI photoionization rate ranges from 5% to 17% over the interval $z = 0 - 6$, significantly smaller.
Fig. 5.—Photoionization rates for the UV background shown in Figure 4. Top left: HI photoionization rates including the contribution from recombinations. The total (quasars+stars) photoionization rate is compared to the value inferred from the Lyα forest flux decrement (Faucher-Giguère et al. 2008a,b). Top right: ratio of the total HI photoionization rate to the value obtained neglecting recombination emission. The bottom panels are analogous but for HeII ionizing radiation. In this case, quasars are the only contributors. The dashed portion of the \( \Gamma_{\text{HeII}}/\Gamma_{\text{HI}} \) curve at \( z > 4 \) indicates a regime of poor numerical convergence (see §5.2) and the turnover at \( z \sim 5 \) is likely an artifact.

The fractional contribution of HeII recombinations to the HeII photoionization rate is also relatively small for the same reason, but it is more difficult to calculate accurately at redshifts \( z \gtrsim 4 \) in our model. In order to obtain an accurate value, in addition to the HeII LyC reemission line to be well resolved on the computational frequency grid, the mean free path of HeII ionizing photons must also be well resolved by the redshift grid. In our calculation, quasars produce a negligible and rapidly dropping HeII photoionization rate at \( z \gtrsim 4 \) while star-forming galaxies maintain a roughly constant HI photoionization rate. In these conditions, the ratio \( \eta = N_{\text{HeII}}/N_{\text{HI}} \) tends to infinity and the HeII mean free path to zero, making it exceedingly difficult to resolve it. Fortunately, the total HeII photoionization rate in this regime is so small that its fractional enhancement from recombinations is of little practical importance. Moreover, in this regime HeII reionization may well be still underway and the HeII ionizing background consequently modified, as elaborated on in §7. In Figure 5 we indicate the portion of poor convergence by a dashed curve segment; the turnover of \( \Gamma_{\text{HeII}}/\Gamma_{\text{HI}} \) around \( z \sim 5 \) is likely an artifact and we in fact expect it to continue to increase slightly toward higher redshifts owing to the reduced leakage (§6.2).

The fractional contribution of HeII recombinations to the HeII photoionization rate is also relatively small for the same reason, but it is more difficult to calculate accurately at redshifts \( z \gtrsim 4 \) in our model. In order to obtain an accurate value, in addition to the HeII LyC reemission line to be well resolved on the computational frequency grid, the mean free path of HeII ionizing photons must also be well resolved by the redshift grid. In our calculation, quasars produce a negligible and rapidly dropping HeII photoionization rate at \( z \gtrsim 4 \) while star-forming galaxies maintain a roughly constant HI photoionization rate. In these conditions, the ratio \( \eta = N_{\text{HeII}}/N_{\text{HI}} \) tends to infinity and the HeII mean free path to zero, making it exceedingly difficult to resolve it. Fortunately, the total HeII photoionization rate in this regime is so small that its fractional enhancement from recombinations is of little practical importance. Moreover, in this regime HeII reionization may well be still underway and the HeII ionizing background consequently modified, as elaborated on in §7. In Figure 5 we indicate the portion of poor convergence by a dashed curve segment; the turnover of \( \Gamma_{\text{HeII}}/\Gamma_{\text{HI}} \) around \( z \sim 5 \) is likely an artifact and we in fact expect it to continue to increase slightly toward higher redshifts owing to the reduced leakage (§6.2).

The total HI photoionization rate matches the value \( \Gamma_{\text{HI}} = (0.5 \pm 0.1) \times 10^{-12} \text{ s}^{-1} \) derived from the Lyα for-
est at $z = 2 - 4.2$, subject to the constraint that quasars must contribute a large fraction near their peak (Faucher-Giguère et al. 2008a). This was done by normalizing the nominal quasar contribution (§5.1) by a factor of 0.36 and normalizing the stellar contribution so as to provide the rest of the ionizing photons. The renormalization of the quasar contribution can be justified by uncertainties in the mean free path of ionizing photons, in their escape fraction, and in the quasar spectral template (see discussion in Faucher-Giguère et al. 2008b). These uncertain factors enter in the conversion from the quasar luminosity to the photoionization rate. Since we wish to reproduce the more robustly constrained photoionization rate measured from the Ly$\alpha$ forest, we adjust the normalization accordingly.

Fig. 6.— Effects of parameters on the calculated spectrum. Top left: varying the constant ratio $\zeta = N_{\text{HeI}}/N_{\text{HI}} = 0, 0.001, 0.005, 0.01, 0.05, \text{ and } 0.1$. Top right: varying the HI column density distribution power-law index $\beta = 1.2, 1.3, 1.4, 1.5, 1.6 \text{ and } 1.7$. Bottom left: varying the stellar spectral index $\alpha_{\star} = 1.0, 1.5, 2.0, 2.5, 3.0, 3.5, \text{ and } 4.0$. Bottom right: varying the quasar spectral index $\alpha_{\text{QSO}} = 0.5, 1.0, 1.5, \text{ and } 2.0$. In each panel, the curves correspond to these values from the top to the bottom. For realistic values of $\zeta$ (§3.2 and Fig. 1) for a background spectrum arising from stars and quasars, the effect of HeI is small. The column density distribution power law $\beta$ determines the spectral hardening just shortward of the ionization edges. The stellar and quasar spectral indices determine the spectral slope of the background. For fixed emissivity at the Lyman limit, the stellar spectral index has only a modest effect on the amplitude of the spectrum because it is truncated at 4 Ryd. The quasar spectral index, assumed to extend to infinity, has a more drastic overall impact toward high energies. Recombination emission has been omitted for clarity of presentation.

6. DEPENDENCES ON INPUT PARAMETERS

Even after fixing the stellar and quasar emissivities for our fiducial model, the spectrum calculations depend on a number of parameters. It is useful to investigate how the calculated spectrum and its integrals depend on these as their values are only known to limited precision. This also provides a physical understanding of the shape of the calculated spectra. We begin by considering the dependences of the overall ionizing background spectrum in §6.1 and focus on the recombination contribution in §6.2.

6.1. Overall Spectrum
In Figure 7 we show how the spectrum changes when the constant ratio $\zeta = N_{\text{HeI}}/N_{\text{HI}}$, the HI column density distribution power-law index $\beta$, and the stellar and quasar spectral indices $\alpha_*$ and $\alpha_{\text{QSO}}$ are individually varied. In each case, all other parameters are fixed to the fiducial model of the previous section. Even for a constant ratio $\zeta = 0.1$, a factor more than one hundred times that expected in our fiducial calculation (9.2), HeI absorbs only a very small fraction of the spectrum shortward of its ionization edge. It is therefore a good approximation to neglect it in our cosmological calculations. The HI column density distribution power-law index $\beta$ determines the spectral hardening just above the ionization edges following $\alpha \rightarrow \alpha - 3(\beta - 1)$ (Appendix D) as well as the depth of the absorption edges. Note that the depth of the HeII absorption edge is more sensitive to $\beta$; this arises because the column density distribution is normalized to the abundance of HI Lyman limit systems (9.2) so that it is fixed in these calculations while the abundance of the HeII Lyman limit systems varies. The stellar and quasar spectral indices simply determine the spectral slopes of the background prior to hardening. For fixed emissivity at the Lyman limit, the stellar spectral index has only a modest effect on the amplitude of the spectrum because it is truncated at 4 Ryd. The quasar spectral index, assumed to extend to infinity, has a more drastic overall impact toward high energies: as $\nu \rightarrow \infty$ and spectral hardening becomes negligible, different spectral indices result in a $J_\nu$ ratio of $(\nu/\nu_{\text{HI}})^{\alpha_{\text{QSO},1} - \alpha_{\text{QSO},2}}$. At 10 keV, for example, this ratio is $75^5$ for $\alpha_{\text{QSO},1} = 1.5$ and $\alpha_{\text{QSO},2} = 0.5$; redshifted from $z = 2$ to $z = 0$, this falls in the bandpass of x-ray observatories such as Chandra and XMM-Newton. The cosmic x-ray background may therefore be a powerful probe of high-energy quasar spectral energy distribution.

In Figure 7 we explore how the hydrogen photoionization rate is affected by the redshift evolution of the column density distribution. In the left panel, we vary the redshift at which the redshift evolution of the column density distribution flattens (9.2) from $z_{\text{low}} = 0$ to $z_{\text{low}} = 2$. Interestingly, this has a minimal impact on the redshift evolution of the photoionization rate even if it does significantly change the mean free path of HI ionizing photons at these redshifts. This is easily understood as a consequence of the fact that the universe effectively becomes transparent at a “breakthrough” redshift $z_{\text{pt}} \sim 2$ (Madau et al. 1999), below which the mean free path becomes so large the local ionizing background is not limited by the latter but by the cosmological horizon. As shown in the right panel, the high-redshift $\Gamma_{\text{HI}}$ declines more rapidly with more a rapid increase in the abundance of absorbers with redshift, or large $\gamma$, translating into a more rapidly diminishing mean free path.

6.2. Recombination Contribution

The contribution of recombinations to the photoionization rates, $\Gamma_{\text{with rec}}/\Gamma_{\text{no rec}}$, is a subtle question as it depends on several factors. It not only depends on the number of reemitted ionizing photons integrated over the distribution of absorbers (9.4) but also crucially on the energy at which these photons are reemitted as well as on their redshifted
Fig. 8.—Dependences of the recombination contribution on HI photoionization rate. Shown are ratios of the total HI photoionization rate, including recombination emission, to the same calculation ignoring recombination emission. In all cases, the sources of the ionizing background are fixed to the fiducial model of §5, but we vary the parameters of the column density distribution and the temperature of the absorbers. Top left: $C = 0.125, 0.25, 0.5, 0.75,$ and 1 from bottom up. Top right: $\beta = 1.2, 1.3, 1.4, 1.5, 1.6$ and 1.7 from bottom up. Bottom left: $T = 1.0, 1.5, 2.0, 2.5, 3.0, 3.5,$ and $4.0 \times 10^4$ K from bottom up. Bottom right: Haardt & Madau (1996) column density distribution with different redshift evolutions in the optically thin and optically thick regimes.

The LyC recombination line processes, most important for the boosting the ionization rates, reemit ionizing photons just above the ionization edges of HI or HeII. Since the ionizing background at a given point is sourced along its past light cone, its photons have generally redshifted slightly from their emission energy. As a result, many recombination photons with initial energy just above their corresponding ionization edges quickly redshift below these edges and are lost as contributors to the ionization rates. The fraction of ionizing recombination photons lost in this way depends on two factors: 1) the recombination line profile which determines how far above the ionization edge an ionizing photon is reemitted and 2) the mean free path of ionizing photons which determines how long the photons have to redshift before they are absorbed. In the limit of a mean free path of zero length, the recombination photons cannot redshift before they are reabsorbed and no photons are lost; as the mean free path increases, more photons leak out of the ionizing range. Similarly, a narrow line profile concentrates the recombination photons just above the ionization edges, leading to a high probability of leakage, while a wider one allows them to remain longer in the ionizing range. Since the mean free path of ionizing photons is determined by the column density distribution and the recombination line width is determined by the temperature of the absorbers, these are important parameters for the recombination contribution. Finally, as recombination photons are reemitted at energies above the ionization edges and subsequently redshift, the frequency dependence $\sigma_i(\nu) \propto \nu^{-3}$ of the photoionization cross section changes the weight they receive in the photoionization rates.

All these effects are self-consistently treated when solving the radiative transfer equation \[ \nabla \cdot \left( \kappa \nabla \phi \right) + \Phi = 0 \]. Figure 8 shows how much the HI photoionization rate is increased by recombination emission as a function of the normalization $C$ of the column density distribution, its power-law slope $\beta$ (see eq. 5), and the temperature $T$ of the absorbers. We also show the case of the column density distribution assumed by Haardt & Madau (1996), in which optically thin
and optically thick absorbers have different redshift evolutions, leading to a redshift-dependent effective slope of the distribution (steeper at high redshifts).

Because the mean free path decreases with increasing abundance of Lyman limit systems (the normalization $C$), fewer recombination photons leak out of the ionizing range and so the ratio of the photoionization rate with and without recombinations, $\Gamma_{\text{HI}}^{\text{with rec}}/\Gamma_{\text{HI}}^{\text{no rec}}$, increases. The ratio also increases with the steepness of the column density distribution since more recombinations occur in optically thin systems, from which practically all the recombination photons escape into the IGM, as opposed to in optically thick systems that trap a large fraction. Higher gas temperatures result in wider recombination lines so that fewer photons are lost owing to redshifting as well as a higher fraction of recombinations directly to the ground state ($\alpha_{\text{HI},n=1}(T)/\alpha_{\text{HI},n=1}(T)$; Appendix C). A competing effect is that the recombination photons of high-temperature absorbers tend to have higher energies and receive less weight in the photoionization rate. The net effect is however relatively weak on $\Gamma_{\text{HI}}$ with recombination.

The previous calculations have implicitly assumed that the universe is reionized in both HI and HeII. This assumption is most evident in the case of HI, for which we have used a column density distribution measured from the $z \lesssim 4$ Ly$\alpha$ forest. The assumption creeps in for HeII reionization during which there are large HeII patches in which the HeII photoionization rate is very low in comparison to within ionized bubbles. In each region, the mapping between $N_{\text{HI}}$ and $N_{\text{HeII}}$ depends on the local spectrum and will in general be very inhomogeneous. The IGM opacity to HeII ionizing photons will therefore be poorly approximated by using a globally-averaged spectrum to map from $N_{\text{HI}}$ to $N_{\text{HeII}}$. In this work, we do not attempt to model HI reionization (and the likely simultaneous reionization of HeI), which occurs at the limit or beyond the present observational reach at $z > 6$ (e.g., Fan et al. 2006a; Dunkley et al. 2008).

In Appendix C we develop a quantitative analytic model that captures and clarifies these effects and agrees well with the full numerical calculations presented here.

### 7. Reionization Events

The previous calculations have implicitly assumed that the universe is reionized in both HI and HeII. This assumption is most evident in the case of HI, for which we have used a column density distribution measured from the $z \lesssim 4$ Ly$\alpha$ forest. The assumption creeps in for HeII reionization during which there are large HeII patches in which the HeII photoionization rate is very low in comparison to within ionized bubbles. In each region, the mapping between $N_{\text{HI}}$ and $N_{\text{HeII}}$ depends on the local spectrum and will in general be very inhomogeneous. The IGM opacity to HeII ionizing photons will therefore be poorly approximated by using a globally-averaged spectrum to map from $N_{\text{HI}}$ to $N_{\text{HeII}}$. In this work, we do not attempt to model HI reionization (and the likely simultaneous reionization of HeI), which occurs at the limit or beyond the present observational reach at $z > 6$ (e.g., Fan et al. 2006a; Dunkley et al. 2008).

The reionization of HeII was however probably delayed until the rise of the quasar luminosity function, at redshifts that are immediately accessible to observations and some understanding of its effects can be obtained by studying the ratio $\eta = N_{\text{HeII}}/N_{\text{HI}}$. In fact, while stellar spectra are theoretically expected to have a strong break at the HeII ionization edge and therefore have little impact on the HeII ionization state, quasars have power-law far-UV spectra that extend well into the x-rays (§5.1). Theoretical calculations based on the quasar luminosity function in fact indicate that quasars can reionize HeII by $z \sim 3 - 4$ (e.g., Sokasian et al. 2002; Wyithe & Loeb 2003; Furlanetto & Oh 2008; Faucher-Giguère et al. 2008b). A number of lines of evidence, based HI and HeII Ly$\alpha$ forests as well as on the evolution of metal line ratios, also suggest that the IGM is undergoing changes that could be associated with HeII reionization at these redshifts (for a review of these lines of evidence, see Faucher-Giguère et al. 2008d). While alternative candidate sources of HeII reionization exist—such as possible HeII ionizing emission from galaxies (e.g., Furlanetto & Oh 2008), high-redshift x-rays (e.g., Oh 2001b; Ricotti & Ostriker 2004), or thermal emission from shock heated gas (Miniati et al. 2004) —quasars are the best established and most likely. Large fluctuations observed in the HeII ionizing background toward $z = 3$ which can be explained by the small number density of bright objects, also lend support to the quasar hypothesis (Zheng et al. 2004; Shull et al. 2004; Bolton et al. 2006) and we will therefore concentrate on this scenario.

#### 7.1. The Ionizing Background During HeII Reionization

Recently, McQuinn et al. (2008) performed detailed radiative transfer simulations of HeII reionization in large boxes up to 430 comoving Mpc on a side (for previous simpler treatments, analytic and numerical, see Sokasian et al. 2002; Bolton et al. 2004; Gesler et al. 2005; Paschos et al. 2007; Furlanetto & Oh 2008; Bolton et al. 2008). These simulations used realistic models for the quasar sources based on the luminosity function of Hopkins et al. (2007) and with physically and empirically motivated prescriptions for the triggering of quasars in massive halos as well as of quasar light curves (see, e.g., Hopkins et al. 2006a; 2006; 2008). A striking result of this work is the remarkable complexity of HeII reionization, in particular of the HeII ionizing radiation field, likely rendering the detailed resulting structure beyond analytic tractability. Nevertheless, some intuition on the spectrum and magnitude of the ionizing background during HeII reionization can be gained by considering idealized cases. We consider two such cases: 1) a single quasar at the center of an isolated ionized bubble and 2) a point in a large HeII patch that has yet to be reionized.

Key insight into the ionizing background is gained by considering relevant physical scales. The left panel of Figure 11 compares the mean free paths (calculated as in Appendix D) of 1 Ryd (HI ionizing) and 4 Ryd (HeII ionizing) photons to the mean separation between the sources of the ionizing background, while the right panel shows scales relevant to understanding the possible effects of HeII reionization by quasars at $z \sim 3 - 4$. The HeII ionizing mean free paths are calculated by converting the HI column densities to HeII assuming a constant $\Gamma_{\text{HI}} = 0.5 \times 10^{-12}$...
and the comoving distance between $z$ fraction solid curve. The dashed curves show the mean free path of high-energy HeII ionizing photons versus redshift assuming a constant ionized rate, is generally smaller than the mean free path of 1 Ryd HI ionizing photons since even quasars produce fact, the mean free path of HeII ionizing photons at these energies, which depends on the local HeII photoionization possible effects of HeII reionization by quasars at $z \sim 3 - 4$. The comoving Bubble radius $c(1+z)/H(z)$ is indicated by the thick solid curve and the comoving distance between $z = 3$ and $z = 4$ spatial surfaces, labeled the “thickness of HeII reionization”, is shown by the thinner solid curve. The dashed curves show the mean free path of high-energy HeII ionizing photons versus redshift assuming a constant ionized fraction $x_i = 0.5$ and that the HeII is uniform distributed, $\Delta_{\text{mfp}}(z) \equiv [\sigma_{\text{HeII}}(\nu) n_{\text{HeII}}(z)]^{-1}$, for different energies. The gray shaded area indicate typical HeIII ionized bubble radii during HeII reionization.

$s^{-1}$ and varying $\Gamma_{\text{HeII}}$. Since emission from star-forming galaxies provides most of the hydrogen photoionization rate at $z \gtrsim 3$ (§3) and the mean separation between $L^*$ galaxies is much smaller than the HI ionizing mean free path at all redshifts $z \lesssim 6$ considered,$^5$ it is a good approximation to treat the stellar emissivity as a uniform volume average as in equation 2. It is also similarly the case for HI ionizing quasar emissivity at redshifts $z \gtrsim 3$, where quasars are relatively abundant and the HI ionizing mean free path large, though with larger fluctuations expected from the smaller number of quasars within each mean free path (for more detailed studies of UV background fluctuations, see Zuo 1992b,a; Fardal & Shull 1993; Croft et al. 1999, 2002; Gnedin & Hamilton 2002; Meiksin & White 2003, 2004; Bouwens et al. 2007; Reddy et al. 2008). For the mean spacing between quasars, the dotted curves correspond to different lower $B$-band luminosity cuts and are calculated using the Hopkins et al. (2007) luminosity function. From bottom up, $L_B \gtrsim 10^{40}, 10^{42}, 10^{44}, 10^{46}$, and $10^{48}$ erg s$^{-1}$. The right panel shows scales relevant to understanding the possible effects of HeII reionization by quasars at $z \sim 3 - 4$. The comoving Bubble radius $c(1+z)/H(z)$ is indicated by the thick solid curve and the comoving distance between $z = 3$ and $z = 4$ spatial surfaces, labeled the “thickness of HeII reionization”, is shown by the thinner solid curve. The dashed curves show the mean free path of high-energy HeII ionizing photons versus redshift assuming a constant ionized fraction $x_i = 0.5$ and that the HeII is uniform distributed, $\Delta_{\text{mfp}}(z) \equiv [\sigma_{\text{HeII}}(\nu) n_{\text{HeII}}(z)]^{-1}$, for different energies. The gray shaded area indicate typical HeIII ionized bubble radii during HeII reionization.

The situation is however quite different beyond 4 Ryd, where continuum opacity owing to HeII dominates. In fact, the mean free path of HeII ionizing photons at these energies, which depends on the local HeII photoionization rate, is generally smaller than the mean free path of 1 Ryd HI ionizing photons since even quasars produce relatively few photons above 4 Ryd. For example, near the peak of the quasar luminosity function at $z = 2.1$, $S = \Gamma_{\text{HI}}/\Gamma_{\text{HeII}} = 140$ (Bolton et al. 2006). The relative rarity of quasars and shortness of the HeII ionizing mean free path combine to create a situation in which often a single bright quasar contributes to the local HeII ionizing flux. Prior to the complete reionization of HeII, ionized bubble walls will further limit the exposure of a given point to the HeII ionizing fields of distant quasars. The radii of HeII bubbles depend, at least until they percolate, on the ionizing luminosity of the central quasars and the duration for which these have been shining. This gives rise to a wide range of scales, depending on the specific quasar model, but by the middle of HeII reionization (determined by an ionized fraction $x_i \sim 0.5$) bubble radius $R_b \sim 10 - 100$ comoving Mpc (corresponding to a few to 20-25 proper Mpc at $z = 3 - 4$) are representative (e.g., Furlanetto & Olm 2008; McQuinn et al. 2008). A volume average uniform emissivity is then clearly inappropriate.

$^5$ At redshifts $z \gtrsim 4$, the estimated mean free path relies on an extrapolation of the measured column density distribution and so the conclusion should accordingly be treated with caution. In particular, the conclusion is likely to break down if HI reionization ends at $z \approx 6$ (e.g., Fan et al. 2002, 2006b).
I\textsubscript{\nu}/I\textsubscript{\nu,HeII}

\begin{equation}
\frac{I\nu}{I\nu,\text{HeII}} = e^{\tau\nu} e^{-\tau\nu,\text{HeII}} \frac{[\sigma\text{HeII}(\nu)/\sigma\text{HeII}(\nu,\text{HeII})]}{\sigma\text{HeII}(\nu,\text{HeII})} \approx \left(e^{-\tau\nu,\text{HeII}}\right)^{\nu/\nu,\text{HeII}}^{-3},
\end{equation}

where the last equality holds approximately just above the HeII ionization edge and we have neglected the fractionally small HI continuum opacity. It follows that the magnitude of the specific intensity is set by the optical depth at the HeII ionization edge to the source, with the spectral shape entirely determined by the frequency dependence of the photoionization cross section at a given optical depth.

In the left panel of Figure 10, we show a quasar spectrum \( I\nu(r = 0) \propto \nu^{-1.6} \) is hardened as a function of \( \tau\nu,\text{HeII} \), the optical depth at the HeII ionization edge from the source. The curves are pictorially labeled assuming a HeII ionizing mean free path comparable to the HeIII bubble size, so that \( \tau\nu,\text{HeII} \sim 1 \) is near the edge of an isolated bubble centered on the quasar. We also show a \( z \sim 2 \) post HeII reionization case in which the mean free path is sufficiently large to contain several quasar sources, with the HI column density distribution and softness parameter \( S = \Gamma\text{HI}/\Gamma\text{HeII} = 140 \) measured at \( z \approx 2 \) (Bolton et al. 2006). This limit is representative of the hardening in the calculations of 5. The dashed curves show the hardened spectrum at different optical depths from a central quasar at the center of an isolated HeII bubble. From the thinnest to the thickest curve, \( \tau\nu,\text{HeII} = 0.1, 0.5, 1, 2, \) and 100. The curves are pictorially labeled assuming a HeII ionizing mean free path comparable to the bubble size, from close to the quasar to toward the edge of a large bubble and inside a HeII patch. Right: Illustration of the absolute effect of HeII attenuation on the full background spectrum. In addition to the spectral hardening, the spectrum is exponentially suppressed above the HeII ionization edge. Recombination reemission is omitted here but discussed in 7.2.

7.1.1. Quasar Within an Isolated Ionized Bubble

Consider first a point within an isolated HeIII bubble occupied by a single quasar at the center, \( r = 0 \). Locally neglecting cosmological effects, the specific intensity of a radial ray is given by

\begin{equation}
I\nu = I\nu(r = 0) e^{-\tau\nu(r)}.
\end{equation}

In addition to the intensity being exponentially suppressed, the spectral shape is altered by the frequency dependence of the optical depth:

\begin{equation}
\frac{I\nu}{I\text{HeII}} = \frac{e^{\tau\nu}}{e^{-\tau\nu,\text{HeII}}} = e^{\tau\nu,\text{HeII}} e^{-\tau\nu,\text{HeII}} [\sigma\text{HeII}(\nu)/\sigma\text{HeII}(\nu,\text{HeII})] \propto \left(e^{-\tau\nu,\text{HeII}}\right)^{\sigma\text{HeII}(\nu)/\sigma\text{HeII}(\nu,\text{HeII})} \approx \left(e^{-\tau\nu,\text{HeII}}\right)^{\nu/\nu,\text{HeII}}^{-3},
\end{equation}

The rarity of quasars implies that around an individual object the specific intensity obeys equation 12 in which a single source is attenuated with distance, rather than a solution involving a volume average emissivity as in equation 2. Why, though, does the ordinary optical depth \( \tau\nu \) enter in equation 12 instead of the effective optical depth \( \tilde{\tau} \) as in equation 2? Any given light ray is always attenuated according to the intervening ordinary optical depth \( \tau\nu \). However, the optical depth between two points separated by a fixed distance (at fixed frequency and redshifts) fluctuates depending on their particular spatial positions because of the stochastic nature of the intervening absorbers.
The effective optical depth captures the average attenuation through $e^{-\tau} = \langle e^{-\tau} \rangle$. It is an appropriate quantity for the ionizing background between 1 and 4 Ryd, where the local intensity is an average over the light received from sources in all directions within one mean free path. The radiation above 4 Ryd at a given point in the vicinity of a quasar prior to and during HeII reionization will often be dominated by the local quasar and therefore be uniquely attenuated as in equation [12]

### 7.1.2. Point in a Large HeII Patch

A point within a HeII patch that has not yet been reionized will see a similarly hardened spectrum, but with a much stronger suppression at the HeII ionization edge owing to the large intervening optical depth. The optical depth at the HeII ionization edge, as a function of redshift and path length $L$, in a medium in which all the helium is assumed to be in the form of HeII is given by

$$
\tau_{\text{neutral}} = \sigma_{\text{HeII}}(\nu_{\text{HeII}}) n_{\text{HeII}}(z) L = 318 \left( \frac{1 + z}{4.5} \right)^4 \left( \frac{L}{10 \text{ comoving Mpc}} \right). \quad (14)
$$

In HeII patch, the intensity of the background at the ionization edge is therefore expected to be almost entirely suppressed. As $\nu \to \infty$ and $\sigma_{\text{HeII}}(\nu) \to 0$, however, the optical depth drops quickly and the intensity of the background recovers. The corresponding increase of the mean free path with energy leads to the presence of a spatially smooth high-energy radiation background permeating most of the cosmic volume, as seen for example in the numerical simulations of McQuinn et al. (2008). The right panel of Figure 10 shows how the fiducial spectrum of the ionizing background at $z = 5$, as calculated in §5, is altered shortward of the HeII ionization edge as a function of the intervening optical depth. Note, in particular, the tremendous HeII edge suppression even in the moderate case of $\tau_{\text{neutral}} = 100$.

### 7.2. Recombination Lines during HeII Reionization

The photoionization rate and ionization state of hydrogen are unaffected by the presence of HeII before and during HeII reionization apart from a small contribution to the photoionization rate by photons above 4 Ryd. Consequently, only the HeII recombination processes are significantly modified. Of these, the most important is HeII Ly$\alpha$ which imprints a distinctive line feature at 3 Ryd (Fig. 1). HeII LyC and BalC only slightly smooth the spectrum at the HeII and HI ionization edges, respectively, and contribute only marginally to the photoionization rates (Figs. 2 and 5).

Equations [B7] and [B8] compactly capture the behavior to HeII Ly$\alpha$ reemission. As explained in the previous section, before HeII reionization the background spectrum is almost completely suppressed above 4 Ryd by the large optical depth at these energies. Since HeII Ly$\alpha$ reemission scales with the HeII ionizing spectrum (with saturation in the optically thick limit), it will be absent before HeII reionization. Similarly, no HeII Ly$\alpha$ should arise within HeII patches during HeII reionization. However, HeII Ly$\alpha$ will be reemitted within ionized bubbles illuminated by the local quasars. As HeII reionization proceeds, the distance between neighboring bubbles should quickly become smaller than the mean free path of 3 Ryd ionizing photons (at 1 Ryd, Fig. 9 shows the mean free path to be about 200 comoving Mpc at $z = 3.5$; at 3 Ryd, eq. D3 predicts the mean free path to be longer by a factor of $3^{3(\beta - 1)} = 5$) that governs the attenuation of HeII Ly$\alpha$ radiation. In the regime in which this mean free path contains several ionized bubbles, the volume fraction of reionized HeII can be viewed as the fraction of the IGM reemitting in HeII Ly$\alpha$ and the HeII Ly$\alpha$ reemission line of the background spectrum can be expected to be about this fraction times the fully reionized value.

### 7.3. Heat Input During HeII Reionization

The photons that ionize HeII atoms in general carry more energy than the $h\nu_{\text{HeII}}$ required. The residual energy is converted into kinetic energy of the resulting free electron and HeII nucleus, with the frequent Coulomb collisions leading to rapid thermalization. This process of photoheating is at work at all times and for all species present. Its effect is however much more important during reionization, when atoms are being ionized at a much greater rate. The effects of HeII reionization on the thermal state of the gas in cosmological simulations has so far generally be modeled by artificially boosting the photoionization rate calculated from a prescribed spatially homogeneous background instantaneously (e.g., Bryan & Machacek 2000; Theuns et al. 2002; Jena et al. 2005), or ignoring it altogether. This approach, of limited physical basis, is a serious limitation of these simulations given the growing body of evidence that HeII reionization occurs at observable redshifts $z \sim 3$–4 and is certain to manifest itself to some extent.

While cosmological radiative transfer simulations are beginning to self-consistently treat gas thermodynamics during HeII reionization (e.g., Paschos et al. 2007; McQuinn et al. 2008), it is likely that the vast majority of simulations performed in the near to moderate future will not explicitly incorporate radiative transfer, either due to the computational cost or to the unavailability of an appropriate code. It therefore remains important to develop ways of approximately treating the effects of HeII reionization in those simulations. We examine this problem in

---

6 In reality, the HeII ionization fronts are quite smooth and extended since they are driven by a hard spectrum (e.g., McQuinn et al. 2008). Except at the very beginning, few points have been truly untouched by HeII reionization, but the discussion holds wherever the ionized fraction has not exceeded, say, $z \sim 1/2$. 

---

16 Faucher-Giguère et al.
this section. Specifically, we consider the questions: How much does HeII reionization heat the IGM? Over what timescale? And how can we approximately model its effects in standard cosmological N-body and hydrodynamical codes such as GADGET (Springel et al. 2001; Springel 2005), Hydra (Pearce & Couchman 1997), or Enzo (O’Shea et al. 2004)?

The simple analytic models that follow are motivated by and owe much to the physical picture of HeII reionization suggested by the radiative transfer calculations of McQuinn et al. (2008). We refer to that work for many original insights.

![Figure 11](image.png)

**Fig. 11.**—Total temperature increase owing to HeII reionization photoheating as a function of the maximum absorbed frequency for different spectral indices $\alpha_{UV}$ of the reionizing sources. The “expected range” corresponds to the bulk of HeII reionization occurring between $z = 3$ and $z = 4$ and is shown only for suggestive purposes. Figure 12 presents more rigorous calculations that avoid fixing a hard cutoff frequency based on the HeII reionization history calculated from the quasar luminosity function.

### 7.3.1. Heat Input Calculation

In order to gain physical intuition, we begin with a simplified model. Suppose that all the photons up to frequency $\nu_{\text{max}}$ emitted by a population of sources with intrinsic spectral index $\alpha_{UV}$ are absorbed by HeII atoms. Then the mean energy injected into the IGM per ionization is given by

$$
\langle E_i \rangle = \frac{\int_{\nu_{\text{HeII}}}^{\nu_{\text{max}}} d\nu / (h\nu) (h\nu - h\nu_{\text{HeII}}) \nu^{-\alpha_{UV}}}{\int_{\nu_{\text{HeII}}}^{\nu_{\text{max}}} d\nu / (h\nu) \nu^{-\alpha_{UV}}} = h\nu_{\text{HeII}} \left[ \frac{\alpha_{UV}}{\alpha_{UV} - 1} \frac{(1 - x^{\alpha_{UV} - 1})}{(1 - x^{\alpha_{UV}}) - 1} \right] \approx \frac{h\nu_{\text{HeII}}}{\alpha_{UV} - 1} (1 - \alpha_{UV} x^{\alpha_{UV} - 1}),
$$

where $x \equiv \nu_{\text{HeII}} / \nu_{\text{max}}$ and the last equality holds approximation for $x \ll 1$ and $\alpha_{UV} > 0$. This equation neglects redshifting of the photons before absorption, which is a reasonable approximation if HeII reionization lasts $\Delta z \approx 1$ at $z \sim 3 - 4$ (e.g., Furlanetto & Oh 2006, Faucher-Giguère et al. 2008b, McQuinn et al. 2008). Here, the effects of spectral filtering (e.g., Abel & Haehnelt 1999, Bolton et al. 2004, Tittley & Meiksin 2007, Bolton et al. 2008) are incorporated in the prescribed frequency cutoff $\nu_{\text{max}}$.

If all the helium is initially in the form of HeII and hydrogen is fully ionized, the temperature increase is obtained by distributing the injected energy over all particles. After thermal equilibrium has been reached,

$$
\Delta T_{\text{HeII}} = \frac{2}{3k} \frac{n_{\text{He}}}{n_{\text{tot}}} \langle E_i \rangle = 15550 \text{ K} \left[ \frac{\alpha_{UV}}{\alpha_{UV} - 1} \frac{(1 - x^{\alpha_{UV} - 1})}{(1 - x^{\alpha_{UV}}) - 1} \right] \approx 31100 \text{ K} \left( \frac{0.5}{\alpha_{UV} - 1} \right) (1 - \alpha_{UV} x^{\alpha_{UV} - 1}).
$$

Here, $n_{\text{tot}} = 2n_{\text{H}} + 3n_{\text{He}}$ is the total number density of particles including free electrons. Note that the total number of particles is slightly less before HeII reionization owing to the smaller number of free electrons. The fractional change of $1/16$ is however negligible. Although the use of a sharp frequency cutoff $\nu_{\text{max}}$ is a simplification of the radiative transfer, McQuinn et al. (2008) show that a simple argument like this one gives a good estimate of the heat input determined from detailed radiative transfer simulations.
What is the relevant value of $\nu_{\text{max}}$? A reasonable guess is the value such that the mean free path of photons of this frequency equals the “thickness” of HeII reionization. Photons of higher frequency (and therefore longer mean free path) will typically not be absorbed before HeII reionization is complete. The right panel of Figure 9 shows where the mean free path intersects the thickness of HeII reionization, assuming that the bulk of the latter takes place between $z = 3$ and $z = 4$, for different values of $\nu_{\text{max}}$. For this purpose, we calculate the mean free path $R_{\text{mfp}}(\nu_{\text{max}}) = [\tau_{\text{HeII}}(\nu_{\text{max}})]^{-1}$ assuming homogeneously distributed 50% ionized HeII at $z = 3.5$. Under these conditions we expect $x^{-1} \sim 8 - 10$; Figure 11 shows the corresponding heat input owing to HeII reionization for different value of the spectral index $\alpha_{\text{UV}}$.

Having obtained simple estimates for the total heat input during HeII reionization, we proceed to make the derivation more rigorous, which also allows us to trace the time evolution of the heat injection. Specifically, we replace the sharp frequency cutoff by a calculation taking into account the fraction of photons emitted at each frequency at any given redshift that is absorbed during HeII reionization:

$$< E_{\nu} (z) > = \frac{\int_{z}^{\infty} dt \int_{v_{\text{HeII}}}^{\infty} dv'/(h\nu')(h\nu' - h\nu_{\text{HeII}})C_{\nu'}^{\text{QSO,com}}(z')[1 - e^{-\tau(\nu', z', z'\prime(t))}] \int_{z}^{\infty} dt \int_{v_{\text{HeII}}}^{\infty} dv'/ (h\nu')C_{\nu}^{\text{QSO,com}}(z')[1 - e^{-\tau(\nu', z, z'\prime(t))}]}{\int_{z}^{\infty} dt \int_{v_{\text{HeII}}}^{\infty} dv'/ (h\nu')C_{\nu}^{\text{QSO,com}}(z')},$$

where $dt = (dz' / c)(dl / dz')$ and

$$\tau(\nu', z, z') = \int_{z'}^{\infty} dz'' \frac{dl}{d\nu'} n_{\text{He}}(z'')[1 - y_{\text{HeII}}(z''; \alpha_{\text{UV}})] \sigma_{\text{HeII}}(\nu'' = \nu'(1 + z'') / (1 + z'))$$

is the optical depth encountered by a photon of frequency $\nu'$ emitted at redshift $z'$ before reaching redshift $z$. Here, $n_{\text{He}}$ is the proper number density of helium atoms and a fraction $1 - y_{\text{HeII}}$ given by the reionization state is assumed to be homogeneously distributed in the form of HeII, taken to be the dominant source of opacity. Equation (17) is similar to equation (15) but with the high-frequency cutoff replaced by the smoothly varying fraction of photons absorbed $1 - e^{-\tau}$ for each frequency. In addition, the mean energy injected per ionization is calculated as a function of redshift, which allows us to trace the heat input over time. This expression neglects recombinations to HeII that lead to multiple ionizations per atom but this is justified since these recombinations are rare in fossil HeII regions (Furlanetto et al. 2008).

Since at a given redshift $z$, only a fraction $y_{\text{HeII}}$ of the HeII has been reionized, the temperature increase contributed by HeII reionization at that redshift, neglecting cooling, is given by

$$\Delta T_{\text{HeII}}(z) = \frac{2}{3K} n_{\text{He}} y_{\text{HeII}}(z) / \langle E_{\nu} (z) \rangle.$$

The temperature of a cosmic gas parcel is in general determined by all the processes by which it gains heat and cools as it evolves, including adiabatic heating and cooling, shock heating, photoheating, Compton cooling off microwave background photons, and recombination cooling (e.g., Hui & Gnedin 1997). Instructive intuition can however be gained from idealized solutions.

In the limit of early HI reionization (with the reionization of HeI assumed to proceed simultaneously), the temperature at mean density $\rho_{0}$ reaches a “thermal asymptote” determined by the competition between adiabatic cooling and photoheating and whose value depends on the HeII ionization state. For a power-law background spectrum $J_{\nu} \propto \nu^{-\alpha_{\text{bg}}}$ just above the ionization edges, a good approximation to the thermal asymptote is given by

$$T_{0}^{\text{asymp}}(z) = 2.49 \times 10^{4} K (0.464 + 0.536 y_{\text{HeII}})(2 + \alpha_{\text{bg}})^{-1/1.7} \left( \frac{1 + z}{4.9} \right)^{0.53}$$

(Hui & Haiman 2003). To first order and ignoring inhomogeneities, the effect of HeII reionization is to inject additional heat to each gas parcel. As the universe expands, the extra heat is diluted by adiabatic cooling, $T(z) = T(z')(1 + z)/(1 + z')^{2}$, so that an estimate of the overall temperature evolution in the early HI reionization limit accounting for HeII reionization heat input is given by

$$T(z) \approx T_{0}^{\text{asymp}}(z) + \int_{z}^{\infty} \int_{z'}^{\infty} d\nu' d\tau_{\text{HeII}}(z') \left( \frac{1 + z}{1 + z'} \right)^{2}.$$

Figure 12 shows thermal histories calculated using this equation assuming a background spectral index $\alpha_{\text{bg}} = 0$ and the Hopkins et al. (2007) quasar luminosity function in the $B$-band for different spectral indices of the HeII ionizing sources $\alpha_{\text{UV}}$. Harder spectral indices are seen to result in greater heat injections, which simply owes to the larger fraction of ionizations caused by high-energy photons. Moreover, the magnitude of the total heat input as a function of spectral index is consistent with the simpler estimates using a sharp frequency cutoff shown in Figure 11. At fixed $B$-band luminosity, harder spectral indices result in higher ionizing photon output rates and thus earlier HeII reionization.

The HeII fraction $y_{\text{HeII}}$ in the above equations is obtained by counting the number of HeII ionizing photons emitted by quasars as in Faucher-Giguère et al. (2008b) and we have assumed a gas clumping factor $C = 5$. 

The thermal history calculations of the previous section implicitly assumed that the universe is homogeneous at a mean density and that HeII reionization happens simultaneously throughout. In reality, the IGM is characterized by density fluctuations and the quasars that putatively drive HeII reionization turn on at different times at different locations owing to cosmic variance. These inhomogeneities imply that the IGM temperature is not fully described by a single redshift dependent number but in reality exhibits a temperature-density relation \( T(z; \Delta) \) with some scatter about the mean at each redshift.

In the absence of HeII reionization, Hui & Gnedin (1997) showed that the temperature-density relation at \( z = 2 - 4 \) is well approximated by a power law \( T(z; \Delta) = T_0 \Delta^{\beta} \). In the limit of early HI reionization, \( \beta \to 0.62 \) as a result of the competition between photoheating and adiabatic cooling. We are interested in how this result is modified by HeII reionization. Equation (21) can be generalized to

\[
T(z) \approx T_0^\text{assymp}(z) \Delta^\beta + \kappa \int_{\infty}^{z} dz' \frac{dT_{\text{HeII}}(z')}{dz'} \left( \frac{1 + z}{1 + z'} \right)^2,
\]

where \( \beta \) is set to the value that would be obtained without HeII reionization and \( \kappa \) is a stochastic factor that accounts for the fact that different regions are heated at different times by HeII reionization photoheating. Our task is then reduced to determining the distribution function of \( \kappa \) to estimate the scatter in the temperature-density relation.

One of the results highlighted by the radiative transfer simulations of McQuinn et al. (2008) is that much of the heating during HeII reionization by quasars results from ionizations by the diffuse background of high-energy photons with large mean free paths that penetrate into HeII patches before these are actually reionized by softer photons (for a different picture, see Bolton et al. 2008). In this picture, the longer a given region is exposed to the high-energy background before it is reionized, the more heat it receives; regions that are reionized last tend to be hotter. As an ansatz, again motivated by the work of McQuinn et al. (2008), we may thus posit that \( \kappa \propto t_{\text{exp},\text{eff}} \), where \( t_{\text{exp},\text{eff}} \) is an effective exposure time to the high-energy background. Note, though, that this will not be correct at the very beginning of HeII reionization before the background has had time to diffuse. We denote by \( z_{\text{HeII}}^\text{eff} \) the redshift at which a given gas parcel is reionized in HeII and set

\[
t_{\text{exp},\text{eff}}(z_{\text{HeII}}) = \int_{\infty}^{z_{\text{HeII}}} dt y_{\text{HeII}}(z)(1 - y_{\text{HeII}}(z)).
\]

The effective exposure time is thus the age of the universe at reionization of the gas parcel, weighted by the time-dependent ionized fraction, and saturating as the latter reaches order unity. The motivation for the weighting is...
that the heat injection is not only proportional to the raw exposure time, but also to the intensity of the high-energy background. The ionized fraction $y_{\text{HI}}$ counts the number of ionizing photons emitted and is therefore a tracer of this high-energy background. The $1 - y_{\text{HI}}$ saturation factor approximates the fact the rate of heat input also scales with $n_{\text{HeII}}$ and is thus suppressed toward the end of reionization.

The PDF of reionization redshifts is also straightforwardly approximated from the ionized fraction evolution since the probability of reionization during a redshift interval scales as the rate at which ionizations occur at that time:

$$P(z_{\text{HeII}}; \Delta z) = \begin{cases} \frac{y_{\text{HI}}(z_{\text{HeII}})^{-1} \frac{dn_{\text{HI}}}{dz}}{\Delta z}, & z_{\text{HeII}} \geq z \\ 0, & z_{\text{HeII}} < z \end{cases}.$$  

(24)

Energy conservation requires $\kappa = 1$, so we set $\kappa = \frac{1}{t_{\text{exp}}(z_{\text{HeII}})^{-1}}$ and in this model the scatter in the temperature-density relation ultimately is calculable from the quasar luminosity function. We wish to emphasize that the effective exposure time ansatz in equation [23] was obtained heuristically and certainly does not capture the full complexity of HeII reionization, though it does agree reasonably well with the results of the McQuinn et al. (2008) simulations and provides a simple way to understand them.

Figure [13] shows the evolution of the temperature-density relation in this model for the case of a quasar spectral index $\alpha_{\text{UV}} = 1.5$, with $\alpha_{\text{K3}} = 0$. The mean temperature at mean density $(T(z; \Delta = 1))$, then traces the corresponding curve in Figure [12] by construction. The slope and scatter of the temperature-density relation are however manifest. The underlying slope is set by the early HI reionization limit $T(z_{\text{HI}}; \Delta = 1)$, but the HeII reionization heat input somewhat flattens the mean slope. The flattening arises because at low densities that are optically thin to the high-energy photons the heat deposition is density-independent in the sense that gas parcels of different densities receive the same temperature increment. Since the lower-density elements are initially cooler, the fractional temperature increase is larger for these. In agreement with the simulations of McQuinn et al. (2008), HeII reionization does not produce an isothermal ($\beta = 0$) temperature-density relation. This is, similarly, simply because the initial heat in gas parcels above mean density $(\Delta > 1)$ is significant compared to the HeII reionization heat injection and so the imprint of this initial heat is not erased. Finally, it is worth reemphasizing that this model predicts a large scatter in the temperature-density relation, which may have important consequence for interpreting Ly$\alpha$ forest data. In this model, though, the scatter arises from the scatter in the HeII reionization times for different gas parcels. Locally, neighboring points will be reionized at similar times and we therefore expect the scatter in the temperature-density relation to be significantly reduced.

### 7.3.3. Implementation in Hydrodynamical Codes

Cosmological hydrodynamical simulations usually incorporate the effects of a prescribed UV background on the thermal history of the gas under the assumption of an optically thin plasma (for the relevant equations, see Katz et al. 1996a). This assumption manifestly breaks down during HeII reionization and has led simulators to artificially increase photoheating rates as a rough approximation of the radiative transfer effects. A more physically motivated approach is to artificially increase the temperature of each gas element by an amount $(\Delta T_{\text{HeII}}(z)/dz)\Delta z$ (which is subsequently let cooling) at each time step $\Delta z$ in the simulation, where $\Delta T_{\text{HeII}}(z)$ is pre-computed given the desired HeII reionization history as in equation [19]. This approach misses the scatter and inhomogeneity of the temperature-density relation discussed in the previous section but has the advantage of only requiring an additional term in the temperature equation and adding negligible computational overhead while capturing the time scale and magnitude of the heat input more realistically. It could conceivably be extended to account for spatial inhomogeneities and the scatter in reionization times similarly to semi-analytic models being applied to efficiently model HI reionization (e.g., Zahn et al. 2007). An alternative approach would be to replace the optically thin photoionization and heating rates by “effective” values that can be substituted into the usual optically thin equations to yield the desired result.

Table [2] tabulates both the optically thin photoionization and photoheating rates, and the $\Delta T_{\text{HeII}}$ values to use to model the effects of HeII reionization under our prescription for the quasar model with $\alpha_{\text{QSO}} = 1.6$ employed in the fiducial background spectrum calculations of [14]. In general, the photoheating rate for species $i$ is given by

$$q_i = \frac{1}{4\pi} \int_{\nu_i}^\infty \frac{d\nu}{h\nu} J_{\nu}(\sigma_i(h\nu - h\nu_i)).$$  

(25)

### 8. Comparison with Previous Work

As one of the motivations for our calculation of the ionizing background spectrum was to provide an alternative to the widely-used models of Haardt & Madau (1996) (see also Haardt & Madau 2001) and their informally-released derivatives, it is useful to directly compare our results with these authors.

Before we do so, we wish to emphasize that in this work we attempted to improve on technical aspects of the calculation. In particular, we performed more self-consistent calculations of the ionization structure of individual absorbers ([13] and our treatment of recombination emission ([14] was based on approximating the results of these photoionization calculations rather than on an escape probability formalism. Moreover, all the numerical calculations
Evolution of the temperature-density relation in the model of §7.3.2 for the case of a quasar spectral index $\alpha_{UV} = 1.5$, with $\alpha_{bg} = 0$. The mean temperature at mean density traces the corresponding curve in Figure 12 by construction. The slope and scatter of the temperature-density relation are however manifest. The underlying slope is set by the early HI reionization limit, $T = T_0 \Delta^{0.62}$, but the HeII reionization heat input somewhat flattens the mean slope. The flattening arises because at low densities that are optically thin to the high-energy photons the heat deposition is density-independent in the sense that gas parcels of different densities are heated by the same amount. Since the lower-density elements are initially cooler, the fractional temperature increase is larger for these. HeII reionization does not produce an isothermal temperature-density relation in this model because the initial heat in gas parcels above mean density is significant compared to the HeII reionization heat injection and so the imprint of this initial heat is not erased.

presented here were performed using an independently-developed code and our empirical constraints (§5) were also obtained independently in our previous work. The comparison of the final results against those of Haardt & Madau thus provides an indication of the uncertainty in the resulting spectrum.

In Figure 14, we compare our fiducial model (ignoring HeII reionization) with two models informally released by Haardt & Madau in 2005 (H&M05; F. Haardt 2005, private communication). Both models include a quasar contribution calculated using a Croom et al. (2004) luminosity function. One model in addition includes a stellar contribution calculated using a Bruzual & Charlot (2003) population synthesis code assuming a Salpeter initial mass function, age 0.5 Gyr, constant star formation, and an escape fraction of 10%. We compare both the detailed spectra at redshifts $z = 0$, 3, and 6 and the integrated photoionization rates of HI and HeII versus redshift. For the detailed spectra, the Haardt & Madau models were normalized by a factor of 0.5 to better match our fiducial calculations in the ionizing range. As a non-negligible uncertainty remains in the amplitude of the intergalactic HI photoionization rate (e.g., Bolton et al. 2005; Faucher-Giguère et al. 2008a), it is fair to renormalize the models before comparing them, a procedure which is also frequently used by simulators to match the observed Ly$\alpha$ forest mean transmission. The photoionization rates shown in the last panel have however not been renormalized and so reflect the models as provided.

It is interesting that in spite of the differences in the technical treatment and the independently obtained empirical constraints, our calculations of the spectral shape in the ionizing range (above 1 Ryd) agree quite well with the H&M05 models between $z = 0$ and $z = 3$, suggesting that the calculations are relatively robust in this redshift range. The spectra however diverge increasingly toward higher redshifts. The differences can be attributed to the different assumptions about the ionizing sources in this high-redshift regime. In our model, based on the Hopkins et al. (2007) quasar luminosity function, the quasar contribution drops more rapidly toward $z = \infty$, explaining the lower amplitude of the predicted HeII ionizing intensity. On the other hand, we have assumed a compensating stellar emissivity that leads to a relatively flat total hydrogen photoionization rate (Faucher-Giguère et al. 2008a,b). Although HeII reionization would modify the results above the HeII ionization edge (§7.1), a prediction of our model is a larger ratio of HI to HeII ionizing flux beyond $z \approx 3$.  

Fig. 13.— Evolution of the temperature-density relation in the model of §7.3.2 for the case of a quasar spectral index $\alpha_{UV} = 1.5$, with $\alpha_{bg} = 0$. The mean temperature at mean density traces the corresponding curve in Figure 12 by construction. The slope and scatter of the temperature-density relation are however manifest. The underlying slope is set by the early HI reionization limit, $T = T_0 \Delta^{0.62}$, but the HeII reionization heat input somewhat flattens the mean slope. The flattening arises because at low densities that are optically thin to the high-energy photons the heat deposition is density-independent in the sense that gas parcels of different densities are heated by the same amount. Since the lower-density elements are initially cooler, the fractional temperature increase is larger for these. HeII reionization does not produce an isothermal temperature-density relation in this model because the initial heat in gas parcels above mean density is significant compared to the HeII reionization heat injection and so the imprint of this initial heat is not erased.
A significant difference between our calculations and the original work of Faucher-Giguère et al. (1998) is with the fraction by which recombination emission boosts the photoionization rates. For their original model, Haardt & Madau (1996) found $\Gamma_{\text{HeII}}^{\text{rec}} / \Gamma_{\text{HI}}^{\text{rec}}$ as high as 1.5 and $\Gamma_{\text{HeII}}^{\text{rec}} / \Gamma_{\text{HeI}}^{\text{rec}}$ peaking at 1.7. For our fiducial model, we found recombinations to be much less important for the photoionization rates, with $\Gamma_{\text{HeII}}^{\text{rec}} / \Gamma_{\text{HI}}^{\text{rec}} \lesssim 1.1$ at $z \leq 4$ for both HI and HeII (Figure 8). The boost factor increases somewhat toward higher redshifts as the mean free paths and leakage due to redshifting below the ionization edges decrease, as discussed in §4.2. In the models we explored, we also found that $\Gamma_{\text{HeII}}^{\text{rec}} / \Gamma_{\text{HI}}^{\text{rec}}$ tends to decrease monotonically toward $z = 0$ as the mean free path of ionizing photons increases. Haardt & Madau (1996) however found $\Gamma_{\text{HeII}}^{\text{rec}} / \Gamma_{\text{HeI}}^{\text{rec}}$ to attain a maximum at $z \approx 3$ while $\Gamma_{\text{HeII}}^{\text{rec}} / \Gamma_{\text{HeI}}^{\text{rec}}$ appears relatively constant with redshift. While the analytic model developed in Appendix C helps us understand our numerical results, the discrepancies between between the boost factors found by Haardt & Madau (1996) and ours (both in magnitude and in redshift behavior), are unclear to us. Our results agree better with those of Fardal et al. (1998), who find that recombinations boost the photoionization rates of both HI and HeII by $\sim 20\%$.

Recently, Madau & Haardt (2008) proposed a new effect on the spectrum of the ionizing background which could be important particularly before HeII is reionized. When a large amount of HeII is present, the opacity arising from HeII Ly$\beta$ and higher Lyman-series resonances produces a sawtooth absorption pattern between 3.56 and 4 Ryd and the HeII Ly$\alpha$ reemission line at 3 Ryd is boosted by resulting degraded photons. We do not include this effect in the present work but plan to do so in the future.

### TABLE 2

| $z$  | $\Gamma_{\text{HI}}^{\text{rec}}$ | $\Gamma_{\text{HeII}}^{\text{rec}}$ | $\Delta \Gamma_{\text{HI}}^{\text{rec}}$ | $\Delta T_{\text{HI}}$ |
|------|----------------------------------|-----------------------------------|---------------------------------|-----------------|
| 0.0  | 0.3854                           | 0.0213                            | 1.231 $\times 10^{-4}$          | 0.0832          |

$^a$ Optically thin rates. $^b$ Cumulative temperature increase owing to HeII reionization, which should be incrementally added to gas elements and let cooling to model the heat input ($\approx 20\%$).

### 9. DISCUSSION AND CONCLUSION

In this work, we have revisited the calculation of the UV background spectrum pioneered by Haardt & Madau (1996) and Fardal et al. (1998). The three main improvements over previous work are:

- The implementation of new empirical constraints on the sources of radiation based on a detailed study of intergalactic absorption and updated luminosity functions (Faucher-Giguère et al. 2008b). In our favored fiducial model, star-forming galaxies play a crucial role and dominate the HI photoionization rate at $z > 3$.

- A reexamination of the radiative transfer within individual absorbers and an exploration of the physical dependences of the calculated background. In particular, we perform more self-consistent photoionization calculations including recombination emission, present a new treatment of recombination emission based on them, and clarify
Fig. 14.— Comparison of our fiducial ionizing background model with models informally released by Haardt & Madau in 2005 (H&M05). Both H&M05 models include a quasar contribution based on the Croom et al. (2004) luminosity function. One model in addition includes a stellar contribution calculated using a Bruzual & Charlot (2003) population synthesis code assuming a Salpeter initial mass function, age 0.5 Gyr, constant star formation, and an escape fraction of 10%. First three panels: Detailed spectra at redshifts $z = 0$, 3, and 6. For this comparison, the H&M05 models were normalized by a factor of 0.5 to better match our fiducial calculation. Lower right: Photoionization rates of HI and HeII versus redshift. Here, the H&M05 models were not normalized and so the different amplitudes reflect the difference in the models as provided.

how the net enhancement of the photoionization rates is influenced by redshifting of the recombination photons below the ionization edges and their energy distribution.

- A treatment of the effects of HeII reionization on background spectrum and on the thermal history of the intergalactic medium.

The main argument supporting a UV background dominated by stellar emission beyond $z \approx 3$ is that while the total HI photoionization rate measured from the Ly$\alpha$ forest is remarkably constant between at least $z = 2$ and $z = 4$ (e.g., Paucher-Giguère et al. 2008a,b), the quasar luminosity function is strongly peaked near $z = 2$ (e.g., Hopkins et al. 2007). Thanks to large-scale Lyman break and Ly$\alpha$ line surveys (e.g., Steidel et al. 1999; Sawicki & Thompson 2006; Yoshida et al. 2006; Bouwens et al. 2007; Reddy et al. 2008; Ouchi et al. 2008), star-forming galaxies are now known to exist numerously at these redshifts and are therefore the leading candidates to account for the remaining ionizing photons. The quasar luminosity function and measurements of HeII-to-HI column density ratios however indicate that quasars do contributed a large fraction of a HI photoionization rate are their $z \approx 2$ peak; in our fiducial model, this fraction is $2/3$.

The evidence in favor of a large (and dominant at the highest redshifts) contribution of star-forming galaxies to the ionizing background is supported by related and independent studies. Previous studies of the HI photoionization rate from the Ly$\alpha$ forest (Rauch et al. 1997; Haehnelt et al. 2001; Bolton et al. 2005) have in fact supported this conclusion, though with somewhat more leeway owing to larger statistical error bars. The case has also been made independently by combining direct measurements of the UV luminosity function of galaxies and of their escape fraction (e.g., Steidel et al. 2001; McDonald & Miralda-Escudé 2001; Shapley et al. 2006; Cowie et al. 2008). Metal line studies provide a further line of evidence, indicating that a mix of stars and quasars best fits measured the abundance ratios of various ions including CIV, SIV, and OVI (Boksenberg et al. 2003; Schaye et al. 2003; Aguirre et al. 2004; 2007). In fact, the ionizing spectrum presented herein could be directly confronted against and further constrained by such observations. Theoretical arguments also suggest that star-forming galaxies should dominate early on (e.g., Springel & Hernquist 2003; Hernquist & Springel 2003; Loeb 2008).

Although the fiducial model detailed in §5 fits our observational constraints, it is not at present uniquely determined. As we explore in §6 the background depends on the details of both the sources and sinks of radiation. For instance, we have adopted a hard spectral index $\alpha_\star = 1$ for star-forming galaxies between 1 and 4 Ryd based on the
comparison of theoretical models with observational line diagnostics by Kewley et al. (2001). However, in spite of a few weak detections, the emergent spectral shape of high-redshift galaxies at these energies has yet to be directly measured owing to the large attenuation by the intervening IGM (e.g., Steidel et al. 2001; Shapley et al. 2006). Moreover, present population synthesis models are at odds with one another in their predictions in this energy range (e.g., Kewley et al. 2001; Boksenberg et al. 2003), making it difficult to rely on them with confidence. Perhaps the largest uncertainty with respect to the absorbers is the abundance and redshift evolution of Lyman limit systems, which determine the mean free path of ionizing photons. These are still poorly constrained, especially above $z \approx 4$, and introduce a commensurate uncertainty in the calculation of the amplitude of the ionizing background at these redshifts (e.g., Figure 7).

The total ionizing background receives a contribution from recombinations that reemit other ionizing photons. We reexamined the physics of this recombination contribution. Interestingly, we find that the enhancement of the photoionization rates from recombinations is not simply a function of the number of recombination photons. This arises because many of the recombination photons rapidly redshift and leak below their corresponding ionization edges as well as from their distribution in energy. Focusing on the HI photoionization rate, the main factors determining $\Gamma_{\text{HI}}^{\text{with rec}}/\Gamma_{\text{HI}}^{\text{rec}}$ are the parameters of the column density distribution and the LyC recombination line profile. Shorter ionizing photon mean free paths, relative to the recombination line width, inhibit leakage. Wider recombination lines, associated with higher gas temperatures, on the other hand produce higher-energy photons that receive less weight in the photoionization rate owing to the frequency-dependence of the cross section. The steepness of the column density distribution also plays a role: for steeper distributions, more of the recombinations occur in optically thin absorbers from which essentially all the recombination photons escape into the IGM, in contrast to optically thick absorbers that trap a large fraction. In general, $\Gamma_{\text{HI}}^{\text{with rec}}/\Gamma_{\text{HI}}^{\text{rec}}$ increases toward higher redshifts as the mean free path diminishes and leakage becomes less significant. In Appendix C we give a simple analytical model that quantitatively captures these effects and agrees well with our full numerical calculations. We conclude that there is not a unique answer for how much recombinations boost the ionization rates, but that it depends both on redshift and on the parameters of the absorbers and their distribution.

Our main solutions to the radiative transfer problem assume that the ionizing background is homogeneous. This approximation will in particular break down during the reionization of HI and HeII. As HeII reionization may take place under the action of quasars at immediately accessible redshifts $z \sim 3 - 4$ (e.g., Sokasian et al. 2002; Wyithe & Loeb 2003; Furlanetto & Oh 2008; Faucher-Giguère et al. 2008b), we provide a discussion of its effects on both the spectrum of the ionizing background and on the thermal history of the IGM. In regions that have yet to be reionized, the spectrum is expected to be almost completely suppressed immediately above 54.4 eV by HeII absorption. However, the universe remains relatively transparent at higher energies owing to the frequency-dependence of the photoionization cross section. As the spectrum recovers, a background of $\gtrsim 0.5$ keV photons should thus permeate the entire universe.

Another important effect of HeII reionization is to inject heat into the IGM via photoheating. We provide a simple analytical model to estimate the overall temperature increase owing to HeII reionization based on energy conservation. In this model, which agrees well with the 3-D radiative transfer simulations of McQuinn et al. (2008), the total temperature increase depends most sensitively on the far UV quasar spectral index. For a value $\alpha_{\text{UV}} = 1.3$, the temperature increase could be as much as 15,000 K, though the effect is mitigated by simultaneous adiabatic cooling. Harder spectral energy distributions lead to more energy injection. The model is extended to understand the effects on the temperature-density relation under the ansatz that the local heat input scales with the effective exposure to the high-energy background. The main effects are to flatten the mean temperature-density relation with respect to the early HI reionization limit (Hui & Gnedin 1997) and introduce a large scatter. The flattening arises because the high-energy background heat deposition per atom is independent of the local density: the temperature of initially cooler lower-density regions is increased by the same amount as that of initially hotter ones of higher density. The temperature-density relation does not become fully isothermal as the HeII reionization heat input is comparable to the initial thermal energy of the gas and so the memory of the latter is not erased. In our model, the scatter of the temperature-density relation originates from the scatter in the reionization times of different gas elements and can be calculated from the quasar luminosity function.

What remains to be done? As outlined above, the ionizing background spectrum is not yet uniquely determined and further direct constraints (for example, using metal line ratios) as well as constraints on its sources and sinks (which enter the theoretical calculation) are sure to continue to refine it, especially at the highest redshifts. The theoretical framework itself needs to be improved to take into account the fluctuations in the ionizing background that necessarily exist at some level and are certain to be important at least during reionization events (for work in this direction, see Bolton et al. 2006; Furlanetto 2008, 2009). In this vein, while our idealized discussion of the effects of HeII reionization provides some basic physical understanding, it leaves ample opportunity for improvement. This a particularly exciting area for future progress as studies of HeII reionization are currently blossoming, with much HI Ly$\alpha$ forest data already available and new HeII Ly$\alpha$ forest lines of sight that the Cosmic Origins Spectrograph (Green 2000) to be installed aboard the Hubble Space Telescope is poised to deliver soon (Syphers et al. 2008), and the accompanying surge of theoretical interest. In particular, several groups are now beginning to numerically tackle the full problem of 3-D radiative transfer and its thermal effects.
McQuinn et al. 2008, Maselli et al. 2008. Another interesting observational opportunity for probing the extragalactic radiation background is provided by the newly-launched Fermi Gamma-Ray Space Telescope. Indeed, the intervening extragalactic background light should attenuate the γ-rays from distant sources through electron-positron pair production and thus give us an additional handle on it, particularly below the HI ionization edge (e.g., Madau & Phinney 1996, Oh 2001b, Razzaque et al. 2008).

To facilitate use and extension of the results presented in this work and their comparison with observations, numerical results are available in electronic form upon request.

We thank Hy Trac for useful discussions and Francesco Haardt for comments and questions that helped us clarify the manuscript. We are especially grateful to Matt McQuinn for physical insights on the effects of HeI reionization on the thermal history of the IGM. APPENDIX

A. PHOTOIONIZATION CALCULATIONS

In this appendix, we detail the code used to calculate the photoionization equilibrium structure of individual cosmic absorbers outlined in §3.

We approximate the absorbers as sheets infinite in extent but finite in thickness, with geometry defined in Figure 15. Although this geometry is restrictive, the calculation is otherwise three-dimensional in the sense that it takes into account that rays incident at different angles encounter different optical depths. We assume that the slab is composed of hydrogen and helium, with cosmic mass fractions \( X \) takes into account that rays incident at different angles encounter different optical depths. We take the total specific intensity at any given point to be the sum of the specific intensity along a particular ray will in general depend on the angle \( \theta \) of incidence inside the slab because different rays encounter different optical depths. We take the total specific intensity at any given point to be the sum of

Specifically, we solve the following set of equilibrium equations under external illumination from both sides by an isotropic radiation field of specific intensity \( J_\nu^\infty \) equal to the cosmological \( J_\nu \) at each point in the absorber:

\[
\alpha_{HI}(T)n_{HI}n_e = \Gamma_{HI}n_{HI}, \quad \text{ (A1)}
\]

\[
\alpha_{HeI}(T)n_{HeI}n_e = \Gamma_{HeI}n_{HeI}, \quad \text{ (A2)}
\]

\[
\alpha_{HeII}(T)n_{HeII}n_e = \Gamma_{HeII}n_{HeII}, \quad \text{ (A3)}
\]

subject to the constraints \( n_H = n_{HI} + n_{HeI}, \quad n_{He} = n_{HeI} + n_{HeII}, \quad \) and \( n_e = n_{HI} + n_{HeI} + 2n_{HeII}. \) The photoionization equilibrium assumption is generally accurate as the ionization timescale is much smaller than the Hubble time and collisional processes are negligible at the densities and temperatures considered (Haardt & Madau 1996).

To close the system of equations [A1]-[A3] we must specify how to calculate the photoionization rates. Let \( J_\nu = (1/4\pi) \int d\Omega I_\nu(\theta) \) be the angle average of the total specific intensity at any given point. Then the local photoionization rate for species \( i \in \{ HI, HeI, HeII \} \) is given by

\[
\Gamma_i(x) = 4\pi \int_\nu^\infty \frac{d\nu}{h\nu} \sigma_i(\nu)J_\nu(x). \quad \text{ (A4)}
\]

The specific intensity along a particular ray will in general depend on the angle \( \theta \) of incidence inside the slab because different rays encounter different optical depths. We take the total specific intensity at any given point to be the sum

\[ \rho \text{ is the mean molecular weight of the gas. These are taken to be 1.62 and 0.59, respectively, corresponding to the limit of early HI reionization (Hui & Gnedin 1997) and fully ionized gas of cosmic composition.} \]
of the radiation originating from the external background and of the radiation from the recombination processes to HI and HeII within the absorber calculated as in §4 and Appendix B. Each component is attenuated in magnitude depending on the optical depth from its source following the usual transfer equation.

In particular, our approach explicitly takes into account the coupling between different species arising from the reabsorption of recombination photons by a different species. For example, ionizing HeII LyC recombination photons will in general not only be reabsorbed by HeII, but also by HI and HeI. Because of this explicit treatment of recombinations, case A recombination coefficients are appropriate in equations A1−A3. As HeI is found to play a negligible role in our calculations, we do not treat its recombination processes in detail, but we do approximate their effect by using the case B recombination coefficient in the optically thick regime.

The equations are solved iteratively until convergence better than one part in $10^3$ is attained at each point.

**B. RECOMBINATION EMISSION**

Here we provide the technical details of our treatment of recombination emission from individual absorbers outlined in §4 including the analytic approximations to the self-consistent numerical photoionization results.

**General Formalism**

Consider a generic line recombination process with source function $S_{\nu}^{\text{rec}} \equiv j_{\nu}^{\text{rec}} / \alpha_{\nu}$, where

\[
    j_{\nu}^{\text{rec}} = \frac{\hbar \nu \alpha_{\nu}(T) n_{i+1} n_e \phi_{\text{rec}}(\nu)}{4\pi}
\]

(B1)

is the relevant emission coefficient and $\alpha_{\nu} = \sum_i n_i \sigma_i(\nu)$ is the absorption coefficient accounting for absorption by all species. Here, $\nu_{\text{rec}}$ is the frequency of the recombination line of interest; we make the approximation that the line is sufficiently narrow that it can be represented by a single frequency for energetic purposes and the frequency dependence of the line profile is captured by the function $\phi_{\text{rec}}(\nu)$. We use the subscript “$i+1$” to refer to singly ionized species $i$. For instance, if $i$ is HI, then $i+1$ is HII, and if $i$ is HeII, then $i+1$ is HeIII. Here $\nu_{\text{rec}}$ is the frequency of the recombination photons, $\alpha_{\nu}(T)$ is the effective recombination coefficients (including all channels leading to the transition of interest), and $\phi_{\text{rec}}(\nu)$ is the reemission line profile.

A given ray crossing a slab absorber with incidence angle $\theta$ will emerge with extra recombination photons following the general solution to the radiative transfer equation (e.g., Rybicki & Lightman 1979):

\[
    I_{\nu}^{\text{rec}}(N_{\text{HI}}; \ x = \infty, \ \mu) = \int_0^{\tau_{\nu}(x=\infty)} d(\tau_{\nu}/\mu) e^{-(\tau_{\nu}/\mu)} S_{\nu}^{\text{rec}}(\tau_{\nu}),
\]

(B2)

where $\tau_{\nu}$ is the optical depth normal to the slab and $\mu = \cos \theta$. The recombination intensity can also be calculated in this way at any point $x$ within the slab to model the effects of recombinations on the ionization structure of the slab.
itself ([3] and Appendix A). Since $\partial^2 N/\partial z \partial N_{\text{HI}}$ is the observed column density distribution, the appropriate value of $\mu$ to use in calculating the cosmological emissivity (eq. [5]) is one and we define $I^\nu_{\text{rec}}(N_i) \equiv I^\nu_{\text{rec}}(N_i; x = \infty, \mu = 1)$.

In the optically thin limit $\tau_\nu(x = \infty) \ll 1$,

$$I^\nu_{\text{rec}}(N_{\text{HI}}) \approx \frac{\hbar \nu_{\text{rec}} \alpha_{\text{rec}}(T)}{4\pi} \frac{\alpha_i^4(T)}{\alpha_i^4(T)} N_i \Gamma_i \phi_{\text{rec}}(\nu),$$

so that the recombination emission is proportional to the column density of the absorber ($N_i$), times the number of incident ionizing photons ($\Gamma_i$), times the fraction of recombinations that lead to the recombination process of interest ($\alpha_{\text{rec}}(T)/\alpha_i^4(T)$). As an absorber becomes optically thick, the number of incident photons it absorbs saturates as $1 - e^{-\tau_\nu}$, so that we expect that the recombination emission will also saturate accordingly. As the numerical calculations in Figures 2 and 3 show, this is the case and will be the basis for the analytical approximations to the reemission that we develop next.

**Analytic Approximations**

A good analytic approximation to the emergent reemission from an absorber, capturing the optically thin limit and the optically thick saturation, is given by

$$I^\nu_{\text{rec}}(N_i) = \frac{\hbar \nu_{\text{rec}} \alpha_{\text{rec}}(T)}{4\pi} \frac{\alpha_i^4(T)}{\alpha_i^4(T)} \min(N_i, N_{\text{i,thresh}}) \Gamma_i \phi_{\text{rec}}(\nu),$$

where and $N_{\text{thresh}}$ is a threshold column density, near the optically thick transition, at which the recombination intensity saturates. To make the approximation smoothly varying with column density, it is convenient to make the replacement $\min(N_i, N_{\text{i,thresh}}) \rightarrow N_{\text{i,thresh}}(1 - e^{-N_i/N_{\text{thresh}}})$, which we do throughout in our numerical evaluations. By inspection, we find that $N_{\text{HI,thresh}} = 10^{16.75}$ cm$^{-2}$ and $N_{\text{HeII,thresh}} = 10^{17.3}$ cm$^{-2}$ give good approximations to the full numerical results for the HI LyC and HeII LyC processes, respectively.

For HeII BalC reemission, a more robust approximation is obtained by noting that in the optically thick regime, the absorbers have a “skin” (analogous to a region behind an ionizing front) that is nearly uniform in HI and HeII. While the recombinations are to HeII, the opacity to the 1 Ryd recombination photons owes to HI. Because this skin is optically thick at the recombination energy, the emergent intensity simply approaches the source function. The value of the source function near the outer edge of the absorber can be approximated using optically thin photoionization abundance ratios:

$$I^\nu_{\text{HeII BalC}}(N_{\text{HI}}) \rightarrow S^\text{HeII BalC(skin)}(N_{\text{HI}}) \approx \frac{\hbar \nu_{\text{HeII BalC}} \alpha_{\text{HeII,n=2}}(T)}{4\pi} \frac{\alpha_i^4(T)}{\alpha_i^4(T)} \min(N_{\text{HI}}, N_{\text{thresh}}) \Gamma_i \phi_{\text{rec}}(\nu)$$

For this process, we approximate the reemission as the minimum of the optically thin limit and this optically thick result.

As Ly$\alpha$ is a resonant transition, its recombination photons will scatter until they destroy the absorber unless they are destroyed by dust, metals, or HI continuum opacity in the case of HeII Ly$\alpha$ which can ionize it. Of particular interest for the destruction by metals is the coincidence between the OIII $\lambda$303.799 line and the HeII Ly$\alpha$ line at 303.783 Å ([Bowen 1934]). Studies of this process (including HI opacity) in the context of dense and enriched planetary nebulae and galactic nuclei ([Weymann & Williams 1969] [Kallman & McCray 1980] [Eastman & MacAlpine 1985]) suggest that the vast majority of the HeII Ly$\alpha$ forest created by recombinations diffuse unimpeded into the IGM for Ly$\alpha$ forest systems. Only the most metal-rich Lyman limit systems and damped Ly$\alpha$ absorbers potentially lose a significant fraction of their HeII Ly$\alpha$ recombination photons to OIII, which should have little global impact. Similarly, only the highest column density and most chemically evolved systems are likely to contain enough dust to efficiently destroy HI Ly$\alpha$ photons. We therefore adopt a simplified treatment of HI and HeII Ly$\alpha$ recombination emission in which we assume that all recombination photons escape into the IGM. Instead of integrating the source function over the absorber, we simply integrate the emission coefficient $j^\text{HI/HeII Ly$\alpha$}$:

$$I^\nu_{\text{HI/HeII Ly$\alpha$}}(N_{\text{HI}}) = \int_{-\infty}^{\infty} dx j^\text{HI/HeII Ly$\alpha$}(x).$$

By the preceding arguments, this is likely a reasonable approximation, but certainly a firm upper bound.

For the Ly$\alpha$ processes, particularly good approximations to the numerical results can be developed as the optically thick limit can be accurately estimated. The key observation is that the fraction of recombinations ultimately leading to the reemission of a Ly$\alpha$ photon is a fixed number (at a given temperature) equal to the sum of all the production channels allowed by the selection rules. Recombinations directly to $n = 1$ produce LyC photons, but unless the recombination occurs near the skin of the absorber this photon will be reabsorbed before escaping and one must account for the probability that it will ultimately result in a Ly$\alpha$ photon. Averaging over angles, the number of
ionizing photons incident from one side of the absorber that are absorbed per unit time per unit area per unit solid angle is given by

\[ \dot{N}_{\text{abs}}(N_{\text{HI}}) = \int_0^1 d\mu \int_{\nu_i}^\infty \frac{d\nu}{h\nu} J_{\nu} \left[ 1 - e^{-\tau_i/\mu} \right] = \int_{\nu_i}^\infty \frac{d\nu}{h\nu} J_{\nu} \left[ 1 - \tau_i \Gamma(1, \tau_i) \right], \]  

where here \( \Gamma(1, \tau_i) \) is the upper incomplete gamma function and is unrelated to the photoionization rate, and \( i \in \{ \text{HI, HeII} \} \) indicates the species of interest. Since in equilibrium the total number of recombinations equals the number of ionizations, the Ly\( \alpha \) recombination in the very optically thick regime can then be written as

\[ \dot{N}_{\text{HI/HeII Ly}\alpha}(N_{\text{HI}}) = f_{\alpha}^{\text{thick}} h\nu_{\text{HI/HeII}} \dot{N}_{\text{abs}}^{\text{Ly}\alpha}(N_{\text{HI}}) \delta(\nu - \nu_{\text{HI/HeII}} \text{ Ly}\alpha), \]  

where \( f_{\alpha}^{\text{thick}} = 0.4 \), set by matching the numerical calculations, accounts for the efficiency of Ly\( \alpha \) photon production and geometrical effects. In general, we again approximate the reemission as the minimum between the optically thin and optically thick results.

Note that an alternative approach for approximating the recombination emission can be derived from the fact that the cosmological emissivity (eq. 8) ultimately does not depend on the detailed function \( \dot{I}_{\nu}^{\text{rec}}(N_i) \) but on its integral over the column density distribution. The part of the integral involving \( N_i \) can thus be factored out and pre-computed for a given column density distribution. Fardal et al. (1998) used an approach along these lines and we also make use of this fact in the next section (eqs C5 and C7) in developing an analytic model for the integrated recombination contribution to the ionizing background.

### C. Analytic Model for the Recombination Contribution to the Ionizing Background

Here we provide a quantitative analytic basis for understanding for the full numerical results on the contribution of recombinations to the ionizing background obtained in §6.2. We focus on the HI photoionization rate and assume that the mean free path is sufficiently short that the local source approximation of equation D1 applies, which is valid at \( z \gtrsim 2 \). Based on [4] and in particular Figure 2, we assume that HI LyC recombination is the dominant process. Following the notation of the main text, let us define \( \Gamma_{\text{HI}}^{\text{rec}} \equiv \Gamma_{\text{HI}}^{\text{th}} + \Gamma_{\text{HI}}^{\text{rec}} \) so that \( \Gamma_{\text{HI}}^{\text{rec}} \) is the portion of the photoionization rate that is contributed by recombinations.

As outlined in §6.2, the recombination contribution depends on several factors. Quantitatively, we write

\[ \frac{\Gamma_{\text{HI}}^{\text{rec}}}{\Gamma_{\text{HI}}^{\text{with rec}}} = \left( \frac{\Gamma_{\text{HI}}^{\text{rec}}}{\Gamma_{\text{HI}}^{\text{with rec}}} \right)_{\text{max}} \times f_{\text{leak}} \times f_{\sigma}, \]  

where the first term is the maximum that would be attained if all the reemitted photons contributed to the ionizing background and all had frequency \( \nu_{\text{HI}} \). \( f_{\text{leak}} \) accounts for leakage of the photons below the ionization edge, and \( f_{\sigma} \) accounts for the frequency-dependence of the photoionization cross section and recombination line profile.

We first consider the maximum contribution by assuming that a negligible fraction of the recombination photons leak below the ionization edge before being reabsorbed and taking the recombination line profile to be a pure \( \delta \)-function, \( \epsilon_{\nu}^{\text{rec}} \equiv \epsilon_{\nu}^{\text{rec}}(\nu - \nu_{\text{HI}}) \). Then,

\[ \Gamma_{\text{HI}}^{\text{rec}} = 4\pi \int_{\nu_{\text{HI}}}^{\infty} \frac{d\nu}{h\nu} J_{\nu} \sigma_{\text{HI}}^{\text{rec}} \epsilon_{\nu}^{\text{rec}}. \]  

Combining equations 8 and B4 for the cosmological recombination emissivity and the special case of HI LyC gives

\[ \epsilon_{\nu}^{\text{rec}} = h\nu_{\text{HI}} \frac{\alpha_{\text{HI}, n=1}(T)}{\alpha_{\text{HI}}(T)} \Gamma_{\text{HI}}^{\text{with rec}} \frac{dz}{d\nu} \int_0^{\infty} dN_{\text{HI}} \frac{\partial^2 N}{\partial z \partial N_{\text{HI}}} N_{\text{HI, thresh}}(1 - e^{-N_{\text{HI}}/N_{\text{HI, thresh}}}) \]  

and therefore

\[ \frac{\Gamma_{\text{HI}}^{\text{rec}}}{\Gamma_{\text{HI}}^{\text{with rec}}} \bigg|_{\text{max}} = \frac{\alpha_{\text{HI}, n=1}(T)}{\alpha_{\text{HI}}(T)} \chi, \]  

where

\[ \chi = \Delta l_{\text{mfp}}(\nu_{\text{HI}}) \frac{dz}{d\nu} \int_0^{\infty} dN_{\text{HI}} \frac{\partial^2 N}{\partial z \partial N_{\text{HI}}} N_{\text{HI, thresh}}(1 - e^{-N_{\text{HI}}/N_{\text{HI, thresh}}}) \]  

is a dimensionless factor whose value depends on how recombination emission saturates with column density relative to absorption (the mean free path term). Using equations 8 and D2 we can express the mean free path at the ionization edge as

\[ \Delta l_{\text{mfp}}(\nu_{\text{HI}}) = \frac{dz}{d\nu} \left[ \int_0^{\infty} dN_{\text{HI}} \frac{\partial^2 N}{\partial z \partial N_{\text{HI}}}(1 - e^{-\sigma_{\text{HI}} N_{\text{HI}}}) \right]^{-1}. \]
and thus
\[ \chi = \frac{\int_0^\infty dN_{\text{HI}} \partial^2 N/\partial z \partial N_{\text{HI}} \left( \sigma_{\text{HI}} N_{\text{HI,thresh}} (1 - e^{-N_{\text{HI}}/N_{\text{HI,thresh}}}) \right)}{\int_0^\infty dN_{\text{HI}} \partial^2 N/\partial z \partial N_{\text{HI}} (1 - e^{-\sigma_{\text{HI}} N_{\text{HI}}})}. \] (C7)

For a power-law column density distribution as in equation 5, the redshift dependence cancels out in the ratio and the integrals over $N_{\text{HI}}$ can be done analytically in terms of gamma-functions. The latter also cancel out, leaving a very simple result:
\[ \chi = (\sigma_{\text{HI}} N_{\text{HI,thresh}})^{2-\beta}. \] (C8)

In Section 3.2, we found that $N_{\text{HI,thresh}} \approx 10^{16.75} \text{ cm}^{-2}$ provides a good approximation for HI LyC. Since $\sigma_{\text{HI}} N_{\text{HI,thresh}} < 1$, equation C8 shows quantitatively how the recombination contribution increases with the steepness of the column density distribution ($\beta$). As noted in Section 6.3, this physically arises because a larger fraction of recombinations occur in optically thin absorbers which return more of their recombination photons into the IGM.

For a hydrogenic atom of integer charge $Z$, the fraction of recombinations that are to level $n$ is
\[ \frac{\alpha_{\text{HI},n}(T)}{\alpha_{\text{HI}}(T)} = \frac{n^{-3} e^{\phi_i/kT} E_i(\phi_n/kT)}{\sum_{i=1}^{\infty} i^{-3} e^{\phi_i/kT} E_i(\phi_i/kT)}, \] (C9)
where $\phi_i = Z^2 \hbar \nu_{\text{HI}} / i^2$ is the ionization energy of level $i$ and $E_i(x) \equiv \int_x^{\infty} dx' e^{-x'}/x'$ (Ciliè 1932).

The actual contribution of recombinations to the ionizing background is smaller because many recombination photons rapidly redshift below the ionization threshold. What fraction of photons are lost through this leakage? Focusing again on LyC recombinations, a photon is reemitted just above the ionization edge with energy $\nu' = \nu_{\text{HI}} + \Delta \nu$, where $\Delta \nu / \nu_{\text{HI}} \ll 1$. Supposing this photon is reemitted at redshift $z_{\text{rec}}$, it will redshift below $\nu_{\text{HI}}$ after traveling a proper distance
\[ \Delta l_{\text{leak}}(z_{\text{rec}}; \Delta \nu) \approx \frac{dl}{dz}(z_{\text{rec}}) \frac{\Delta \nu}{\nu_{\text{HI}}}(1 + z_{\text{rec}}). \] (C10)

The local source approximation of equation D1 is valid because in this regime we can write $J_\nu = (4\pi)^{-1} \int_0^{\infty} d\nu' e^{-\nu'/\Delta l_{\text{mfp}}}$, with the emissivity treated as a constant. The leakage of recombination photons owing to redshifting implies that the emissivity should really integrated over a maximum distance $\Delta l_{\text{leak}}$:
\[ J_{\nu'} = \frac{1}{4\pi} \int_0^{\Delta l_{\text{leak}}} d\nu' e^{-\nu'/\Delta l_{\text{mfp}}} = \frac{1}{4\pi} \Delta l_{\text{mfp}} e_{\nu'}^{\nu_{\text{HI}}} [1 - f_{\text{lost}}], \] (C11)
where $f_{\text{lost}}(z_{\text{rec}}; \Delta \nu) = e^{-\Delta l_{\text{leak}}/\Delta l_{\text{mfp}}}$ is the fraction of recombination photons emitted with frequency above the ionization edge that are lost to redshifting.

The overall fraction of photons lost is then an average over the recombination line profile:
\[ f_{\text{lost}}(z_{\text{rec}}) = \frac{1}{\nu_{\text{HI}}} \int_{\nu_{\text{HI}}}^{\infty} d\nu' \phi_{\text{rec}}(\nu') f_{\text{lost}}(z_{\text{rec}}; \Delta \nu = \nu' - \nu_{\text{HI}}). \] (C12)

The result is simplified if the line profile is taken to be purely exponential, $\phi_{\text{rec}}(\nu') = (\hbar/kT)e^{-\hbar \nu'/kT}$ for $\Delta \nu \geq 0$, in which case
\[ f_{\text{lost}}(z_{\text{rec}}) = \frac{1}{1 + y(z_{\text{rec}}; \Delta l_{\text{mfp}}, T)}, \] (C13)
where
\[ y(z_{\text{rec}}; \Delta l_{\text{mfp}}, T) = \frac{kT/\hbar \nu_{\text{HI}}}{\Delta l_{\text{mfp}}(dz/dl)/(1 + z_{\text{rec}})}. \] (C14)

The mean free path depends on redshift and on the parameters of the column density distribution. Using the analytical expression for $\Delta l_{\text{mfp}}$, we can express $f_{\text{lost}}$ directly in terms of these basic parameters:
\[ f_{\text{lost}}(z_{\text{rec}}; C, \gamma, \beta, T) = \frac{1}{1 + CT(2 - \beta)(1 + z_{\text{rec}})^{1+\gamma} kT/\hbar \nu_{\text{HI}}} \] (C15)
and finally define $f_{\text{leak}} \equiv 1 - f_{\text{lost}}$.

The last term to consider is the suppression factor that arises because the photoionization cross section entering in the photoionization rate from recombinations is frequency-dependent and photons are really reemitted with finite energy above the ionization threshold. This is simply a frequency average of the cross section, over its maximum at $\nu_{\text{HI}}$:
\[ f_{\sigma_i} = \int_{\nu_{\text{HI}}}^{\infty} d\nu' \phi_{\text{rec}}(\nu'/\nu_{\text{HI}})^{-3} = \left(\frac{h \nu_{\text{HI}}}{kT}\right)^3 e^{-h \nu_{\text{HI}}/kT} \Gamma(-2, h \nu_{\text{HI}}/kT), \] (C16)
Fig. 16.—Dependences of the recombination contribution to HI photoionization rate calculated with the analytic model of Appendix C. Shown are ratios of the total HI photoionization rate, including recombination emission, to the same calculation without recombination emission. We vary the parameters of the column density distribution and temperature of the absorbers. Top left: $C = 0.125, 0.25, 0.5, 0.75,$ and 1 from bottom up. Top right: $\beta = 1.2, 1.3, 1.4, 1.5, 1.6$ and 1.7 from bottom up. Bottom left: $T = 1.0, 1.5, 2.0, 2.5, 3.0, 3.5,$ and $4.0 \times 10^4$ K from bottom up. Bottom right: $\gamma = 1.0, 1.25, 1.5, 1.75,$ and 2.0 from bottom up. The first three panels can be directly compared with the corresponding full numerical calculations shown in Figure 8. The main features and dependences are well reproduced by this simple model. The differences at $z \lesssim 2$, where the analytic model is inapplicable, arise because the local source approximation used becomes invalid as the radiation field begins to be limited by the cosmological horizon.

where we have again approximated the recombination radiation to have a purely exponential profile and that the cross section scales as $\nu^{-3}$ just above the ionization edge.

In Figure 16 we combine these analytic results and show how $\Gamma_{\text{HI}}^{\text{with rec}}/\Gamma_{\text{HI}}^{\text{no rec}} = 1/(1 - \Gamma_{\text{HI}}^{\text{rec}}/\Gamma_{\text{HI}}^{\text{with rec}})$ varies as a function of the parameters of the column density distribution and the temperature of the absorbers. Note that the main features and dependences of the corresponding full numerical calculations shown in Figure 8 are well reproduced by this simple model. The differences at $z \lesssim 2$ arise because the local source approximation used in the analytic calculations becomes invalid as the radiation field begins to be limited by the cosmological horizon; the “effective mean free path” is then shorter than the mean absorption distance and more recombination photons are thus in reality retained in the ionizing range.

D. SPECTRAL FILTERING

The spectral index of a radiation background in general differs from the spectral index of its sources owing to filtering along the line of sight. In this section, we explore different filtering cases relevant to the ionizing background in order to provide physical understanding of our numerical solutions of the radiative transfer equation and provide analytical results referred to in the main text.

An important characteristic of the ionizing background at high redshifts is that it is local in the sense that the specific intensity $J_\nu$ depends only on the local value of the specific emissivity $\epsilon_\nu$:

$$J_\nu(z) \approx \frac{1}{4\pi} \Delta mfp(\nu, z) \epsilon_\nu(z).$$ (D1)
Here, \( \Delta l_{\text{mfp}}(\nu, z) \) is the mean free path of photons of frequency \( \nu \) and redshift \( z \) and is given by

\[
\Delta l_{\text{mfp}}(\nu_0, z_0) = \frac{dl}{dz}(z_0) \left( \frac{d\tau(\nu_0, z_0, z)}{dz} \right)^{-1}(z_0)
\]

(D2)

This limit of equation (2) is valid whenever photons are absorbed so close to their point of emission that they redshift only negligibly. For HI ionizing photons of wavelength 912 Å, the “breakthrough” point above which this approximation holds is approximately \( z = 2 \) (Madau et al. 1999). In this regime, cosmological effects are unimportant and calculations can be performed in ordinary Euclidean geometry. Then the effective optical depth at frequency \( \nu \) over a proper length \( l \) at redshift \( z \) can be written as \( \tau(\nu, z, l) \) and \( \Delta l_{\text{mfp}}(\nu, z) = (dl/d\tau)^{-1}. \) A useful analytical expression for the mean free path can be obtained at frequencies where the photoionization cross section \( \sigma_i \propto \nu^{-3} \) and the column density distribution is described by single power laws \( \beta \) and \( \gamma \) (see eq. [5]). In the case of HI,

\[
\Delta l_{\text{mfp}}(\nu_0, z_0) \approx \frac{(\beta - 1)c}{\Gamma(2 - \beta)N_0\sigma_{\text{HI}}^{-1}} \left( \frac{\nu_0}{\nu_{\text{HI}}} \right)^{3(\beta - 1)} \frac{1}{(1 + z_0)^{\gamma + 1}} H(z_0),
\]

(D3)

and it is straightforwardly generalized to any other single ion.

An implicit assumption in equation (D1) (as well throughout much of this paper, such as in eqs. 1 and 2) is that a sphere of radius one mean free path contains sufficiently many sources that their effect is well-captured by the use of a volume-averaged uniform emissivity. This is generally valid when the sources are star-forming galaxies, which are very numerous. Quasars, however, are much rarer and this assumption in general fails. (See Figure 9 and the discussion in [7,1]). We will therefore also consider the case of filtering of radiation from an isolated source. For each case, we will consider both the cases in which the intervening absorbers are uniformly distributed and the one in which discrete absorbers are Poisson-distributed following a column density distribution.

**Uniform Emissivity and Absorbing Material**

In the case in which both the emissivity and the absorbing material are spatially uniform,

\[
J_\nu(z) \approx \frac{1}{4\pi} \Delta l_{\text{mfp}}(\nu, z) \epsilon_\nu(z) \bar{\epsilon}(\nu, z, l) = n_{\text{abs}} \sigma_{\text{abs}}(\nu) l,
\]

so that \( J_\nu(z) \approx \frac{1}{4\pi} \frac{\epsilon_\nu(z)}{n_i \sigma_i(\nu)}. \)

(D4)

where \( n_i \) is the number density of the absorbing material and \( \sigma_i(\nu) \) is its cross section. For photons with \( \nu_{\text{HI}} \leq \nu < \nu_{\text{HeII}} \), the dominant source of continuum opacity owes to HI photoionization, so \( n_i = n_{\text{HI}} \) and \( \sigma_i(\nu) = \sigma_{\text{HI}}(\nu) \). For \( \nu \geq \nu_{\text{HeII}} \), HI continuum opacity is fractional small in the cosmological context and we can take \( n_i = n_{\text{HeII}} \) and \( \sigma_i(\nu) = \sigma_{\text{HeII}}(\nu) \). Since both absorbing ions are hydrogenic, they similarly harden spectra following \( J_\nu \propto \epsilon_{\nu}/\sigma_i(\nu) \approx \epsilon_{\nu} \nu^4 \). The last equality is approximately valid near the ionization edge. At high energies, the photoionization cross section decreases more steeply and the hardening becomes negligible.

**Uniform Emissivity and Discrete Absorbers**

If the emissivity is spatially uniform, but the absorbers are discrete and Poisson-distributed, the result is similar, but with the effectively optical depth calculated from the column density distribution as in equation (3). If the column density distribution of the absorbers follow a power-law \( dN/dN_{\text{HI}} \propto N_{\text{HI}}^{-\beta} \), then just above the ionization edge where the cross section \( \sigma_i(\nu) \propto \nu^{-3} \), the mean free path \( \Delta l_{\text{mfp}}(\nu, z) \propto \nu^{-3(\beta - 1)} \) (Zuo & Phinney 1993; Faucher-Giguère et al. 2008b) and therefore \( J_\nu \propto \epsilon_\nu \nu^{3(\beta - 1)} \). For HI, we may take \( \beta = 1.4 \), as measured by Misawa et al. (2007), in which case the hardening \( \alpha \rightarrow \alpha - 1.2 \) is significantly weaker than the \( \alpha \rightarrow \alpha - 3 \) in the uniform absorbing material case above the HI ionization edge. If the proportionality factor \( \eta \) between \( N_{\text{HI}} \) and \( N_{\text{HeII}} \) were a constant throughout, the radiation above the HeII ionization edge would be identically hardened. However, the complex behavior of \( \eta \) in the optically thick regime (16.2) may alter this result; this behavior is taken into account in our numerical calculations.

**Point Source and Uniform Absorbing Material**

The case of an isolated point source is quite different. In this case, the specific intensity (which can no longer be assumed to be isotropic, so we denote it by \( I_\nu \) instead of \( J_\nu \)), is exponentially suppressed with increasing optical depth from the source:

\[
I_\nu = I_{\nu_0}(l = 0) e^{-\tau_\nu(l)}.
\]

(D5)

We again assume that HI continuum opacity dominates for \( \nu_{\text{HI}} \leq \nu < \nu_{\text{HeII}} \) and that HeII continuum opacity dominates for \( \nu > \nu_{\text{HeII}} \). In each regime, \( \tau_\nu(l) = n_i \sigma_i(\nu) l \). The spectrum is attenuated relative to its value at \( \nu_i \) by a factor

\[
\frac{I_\nu}{I_{\nu_0}} = \frac{e^{-\tau_\nu}}{e^{-\tau_{\nu_i}}} = e^{-\tau_{\nu_i} |\sigma_i(\nu)/\sigma_i(\nu_i)|} \approx (e^{-\tau_{\nu_i}})^{(\nu/\nu_i)^{-3}},
\]

(D6)

where the last equality again holds approximately just above the ionization edge.
Point Source and Discrete Absorbers

For a point source attenuated by Poisson-distributed discrete absorbers, we simply replace the ordinary optical depth by the effective optical depth to obtain the average spectrum:

\[ I_\nu(l) = I_\nu(l = 0)e^{-\tau_\nu(l)}. \]  

(D7)

Drawing on our previous results,

\[ \frac{I_\nu}{I_{\nu_1}} = \frac{e^{-\tau_\nu}}{e^{-\tau_{\nu_1}}} = \bar{\nu}_{\nu_1} e^{-\tau_\nu} \propto (\nu/\nu_1)^{-(\beta+1)}. \]

(D8)

It is worth noting, as explained in \[7.1.1\], that at fixed optical depth from a source the hardening is the same regardless of how (smoothly or discretely) the intervening material is distributed. The different average hardening differs in the discrete case really because of the added stochastic nature of the intervening optical depth at fixed distance.

E. Atomic Physics Values

The radiative transfer calculations in this paper are ultimately rooted in atomic physics. The recombination rates and He I photoionization cross sections are taken from the appendix of Hui & Gnedin (1997). For the Ly\(\alpha\) emission coefficients and the HI and He II photoionization cross sections we take the expressions given by Osterbrock & Ferland (2006). In particular, given the prominent role it plays in our calculations, the photoionization cross section of a hydrogenic atom of atomic number \(Z\) (\(Z = 1\) and \(2\) for HI and He II) is given by

\[ \sigma_i(\nu) = \frac{A_0 (\nu/\nu_1)^4 \exp(4 - [4 \tan^{-1} \epsilon/\epsilon])}{1 - \exp(-2\pi/\epsilon)} \]  

(E1)

for \(\nu \leq \nu_1\) and 0 otherwise. Here,

\[ A_0 = \frac{2^9\pi}{3e^2} \alpha \pi a_0^2 = 6.30 \times 10^{-18} \text{ cm}^2, \]  

(E2)

where \(\alpha\) is the fine structure constant and \(a_0\) is the Bohr radius, \(\epsilon = \sqrt{\nu/\nu_1} - 1\), and \(h\nu_1 = Z^2 h\nu_{\text{HI}} = 13.6 Z^2\) eV. Just above the photoionization edge \(\nu_1\), i.e. for \(\epsilon \ll 1\), \(\sigma_i(\nu) \propto \nu^{-3}\) but the cross section drops faster than a power law as \(\nu \to \infty\), explaining the lack of spectral hardening in this limit.

Also of interest is the recombination line profile for free-bound transitions, which is important in determining the contribution of recombination emission to the ionizing background (\[4\]). The probability that a recombination yields a continuum photon of frequency between \(\nu\) and \(\nu + d\nu\), by definition, is \(\phi_{\text{rec}}(\nu)d\nu\). The velocity \(u\) of the recombining electron relative to the nucleus\(^8\) is related to the frequency by \(h\nu = m_u u^2/2 + h\nu_{\text{rec}}\), where \(\nu_{\text{rec}}\) is the ionization edge frequency. Now, the probability that the recombining electron has velocity between \(u\) and \(u + du\) scales as the probability that an electron in this velocity range recombines when it encounters a nucleus, times the number of electrons with velocity in this range.

If \(\sigma_{\text{rec}}(u)\) is the velocity-dependent recombination cross section, then the first term is \(\propto \sigma_{\text{rec}}(u)u\). In thermal equilibrium, the second term is given by the Maxwell-Boltzmann speed distribution, \(f_{M-B}(u) \propto u^2 \exp(-m_u u^2/2kT)\). Thus,

\[ \phi_{\text{rec}}(\nu)du \propto \sigma_{\text{rec}}(u)uf_{M-B}(u)du. \]  

(E3)

The Milne detailed balance relation relates the recombination cross section to the corresponding photoionization cross section:

\[ \sigma_{\text{rec}}(u) = 2 \left( \frac{h\nu}{m_u u c} \right)^2 \sigma_i(\nu) \]  

(E4)

(e.g., Osterbrock & Ferland 2006). Using the approximation \(\sigma_i(\nu)\)\(^{-3}\), we can solve and find, after normalizing,

\[ \phi_{\text{rec}}(\nu) = \frac{(\nu/\nu_{\text{rec}})^{-1} \exp(-h\nu/kT) \theta(\nu - \nu_{\text{rec}})}{\Gamma(0, h\nu_{\text{rec}}/kT)} \nu_{\text{rec}}. \]  

(E5)

This profile will also be thermal broadened and shifted owing to the peculiar velocity of the emitting gas; these corrections are however negligible in comparison to the width of the recombination line profile. For instance, the recombination line width \(\Delta\nu_{\text{rec}}/\nu_{\text{rec}} \approx kT/\nu_{\text{rec}} \approx 0.13\) for HI LyC at \(T = 2 \times 10^4\) K, while the Doppler broadening at the same temperature \(\Delta\nu_D/\nu_{\text{rec}} \approx 0.002\) and the peculiar velocity shift \(\Delta\nu_{\text{pec}}/\nu_{\text{rec}} \approx 0.0003\) for \(v_{\text{pec}} = 100\) km s\(^{-1}\).
