\textbf{Abstract.} We present an updated version of our standard solar model (SSM) where helium and heavy elements diffusion is included and the improved OPAL equation of state (Rogers 1994, Rogers Swenson \& Iglesias 1996) is used. In such a way the EOS is consistent with the adopted opacity tables, from the same Livermore group, an occurrence which should further enhance the reliability of the model. The results for the physical characteristics and the neutrino production of our SSM are discussed and compared with previous works on the matter.

\textbf{Key words:} The Sun: evolution – The Sun: general – The Sun: particle emission

In addition, updated values of the relevant nuclear cross sections are used and more refined values of the solar constant and age (BP95) are adopted.

Before entering into the argument, let us recall that in recent years helioseismology has added important pieces of information on the solar structure, producing severe tests for standard solar model calculations. According to Christensen-Dalsgaard et al. (1993) one can accurately determine the depth of the solar convective zone and the speed of sound at its bottom:

\begin{equation}
R_b/R_\odot = 0.710 \pm 0.716
\end{equation}

\begin{equation}
c_b = 0.221 \pm 0.225 \ (Mm/s)
\end{equation}

Richard et al. (1996; hereafter RCVD96) recently confirmed the value of $R_b$, finding $R_b/R_\odot = 0.7137$. In addition several determinations of the helium photospheric abundances have been derived from inversion of helioseismological data, with results in the range (see Castellani et al. 1996 and refs. therein):

\begin{equation}
y_{\text{photo}} = 0.233 \pm 0.268.
\end{equation}

The much smaller errors often quoted, reflect the observational frequency errors only. The results actually depend on the method of inversion and on the starting physical inputs (e.g. the EOS), see RCVD96.

Note that, since in building a SSM one is dealing with three free parameters (mixing length, original He content and original $Z/X$), with these three additional constraints ($R_b$, $c_b$ and $y_{\text{photo}}$) no free parameter is left for SSM builders.

After discussing the effect of the physical inputs, we compare our SSM with other recent solar model calculations, all including diffusion of helium and heavy elements, finding an excellent agreement. We present neutrino fluxes and the expected signals in ongoing experiments. A detailed presentation of our new model...
As for the computations, FRANEC has been described in previous papers (see e.g. Chieffi & Straniero 1989, Castellani et al. 1992). Recent determinations of the solar luminosity \(L_\odot = 3.844 \times 10^{33} \text{ erg/s}\) (BP95) and of the solar age \(t_\odot = 4.57 \times 10^9 \text{ yr}\) (BP95) are used. The present ratio of the solar metallicity to solar hydrogen abundance by mass corresponds to the most recent value by Grevesse & Noels (1993): \((Z/X)_{\text{photo}} = 0.0245\).

Following the standard procedure (see e.g. Bahcall & Ulrich 1988), for each set of assumed physical inputs the initial Y, Z and the mixing length parameter \(\alpha\) were varied until the radius, luminosity and \(Z/X\) at the solar age matched the observed values within a tenth of percent or better. We considered the following steps:

a) As a starting model we used the Straniero (1988) equation of state, the version of the OPAL opacity tables available in 1993 (Rogers & Iglesias 1992, Iglesias Rogers & Wilson 1992) for the Grevesse & Noels (1993) solar metallicity ratio, combined with the molecular opacities by Alexander & Fergusson (1994): diffusion was ignored. This model is useful for a comparison with BP95 (without diffusion) which uses the same chemical composition.

b) Next, we introduced the OPAL equation of state. With respect to other commonly used EOS, this one avoids an ad hoc treatment of the pressure ionization and it provides a systematic expansion in the Coulomb coupling parameter that includes various quantum effects generally not included in other computations (see Rogers 1994, Rogers Swenson & Iglesias 1996 for more details).

c) Next, OPAL 1993 tables were substituted with the latest OPAL opacity tables (Rogers & Iglesias 1995), again for Grevesse & Noels (1993) solar metallicity ratio. With respect to Rogers & Iglesias (1992) the new OPAL tables include the effects on the opacity of seven additional elements and some minor physics changes; moreover the temperature grid has been made denser.

d) Furthermore, we included the diffusion of helium and heavy elements. The diffusion coefficients have been calculated using the subroutine developed by Thoul (see Thoul, Bahcall and Loeb 1994). The variations of the abundance of H, He, C, N, O and Fe are followed all along the solar structure; all these elements are treated as fully ionized. According to Thoul, Bahcall and Loeb (1994) all other elements are assumed to diffuse at the same rate as the fully-ionized iron. To account for the effect of heavy element diffusion on the opacity coefficients we interpolated with different total metallicity \(Z=0.01, 0.02, 0.03, 0.04\).

e) As a final point, we investigated the effect of updating the nuclear cross sections for \(^3\text{He}+^3\text{He}\) and \(^3\text{He}+^4\text{He}\) reactions, following a recent reanalysis of all available data (see Castellani et al. 1996, and table 6). For \(S(0)_{24}\), a polynomial fit gives (energy in MeV, \(S\) in MeV barn):

\[
S_{24}(E) = (4.8 - 2.9E + 0.9E^2) \times 10^{-4}.\tag{3}
\]

Alternatively, by using an exponential parametrization, as frequently adopted in the literature, one obtains an equally good fit to experimental data:

\[
S_{24}(E) = 5.1 \cdot 10^{-4} \exp(-0.83E + 0.25E^2).\tag{4}
\]

At the energies of interest, \(E_0 \approx 20\ \text{KeV}\), the second expression yields an S factor larger by about 5%, a value which is indicative of the uncertainty on \(S_{24}\) at these low energies. In the calculations, we used eq. 4.

The resulting solar models are summarized in table 1, which deserves the following comments:

(a \(\rightarrow\) b): the introduction of the new OPAL EOS reduces appreciably the initial helium abundance. The Straniero (1988) EOS underestimates the Coulomb effects neglecting the contribution due to the electrons, which are considered as completely degenerate, whereas the OPAL EOS includes corrections for Coulomb forces which are correctly treated (see Rogers 1994 for more details). The models with Straniero EOS have a higher central pressure and a higher central temperature, and correspondingly a higher initial helium abundance. The effect of an underestimated Coulomb correction was discussed in Turck-Chièze & Lopez (1993). Note that the helium abundance is higher than the helioseismological determination by more than 2\(\sigma\). Moreover, the transition between radiative and convective regions is not correctly predicted by the model, the convective region being definitely too shallow.

(b \(\rightarrow\) c): the updating of the radiative opacity coefficients has minor effects. The surface helium abundance is now within 2\(\sigma\) from the helioseismological determination, but the convective zone is again too shallow.

(c \(\rightarrow\) d): this step shows the effects of diffusion. Helium and heavy elements sink relative to hydrogen in the radiative interior of the star because of the combined effect of gravitational settling and of thermal diffusion. This increases the molecular weight in the core and thus the central temperature is raised. The surface abundances of hydrogen, helium and heavy elements are appreciably affected by diffusion: the initial value \(Y_m = 0.269\) is reduced to the present photospheric value \(Y_{ph,0.238}=0.238\), within 2\(\sigma\) from the helioseismological results. More important,
speed are now in good agreement with helioseismological values. With respect to models without diffusion, in the external regions the present helium fraction is reduced while the metal fraction stays at the observed photospheric value. Thus the opacity increases and convection starts deeper in the Sun. As an example of the diffusion process we show in fig. 1 the time dependence of the He profile and in fig. 2 the present H profile, calculated with and without diffusion.

(d→c): The modifications of our Solar Model arising from the new values of the nuclear cross sections are negligible with respect to the other improvements just presented.

Fig. 1. Time dependence of the He profile of our model e). The He profile at t=4.57 Gyr is that of our “best” standard solar model.

Fig. 2. H profile for a solar model without diffusion (our model c) and with diffusion (our model e).

Our “best” Standard Solar Model, model (e), appears in good agreement with recent calculations (table 3) by several authors, all including microscopic diffusion and using (slightly) different physical and chemical inputs, summarized in table 4. Our ingredients are very close to those of BP95 and one notes a substantial similarity with that model. We only have a slightly lower central temperature, possibly an effect of the different EOS. Among the different models, diffusion looks less efficient in RVCD96, as a consequence of the inclusion of rotational induced mixing.

The predicted neutrino fluxes and signals from our SSM are summarized in table 2. All in all, the results are quite stable with respect to the changes we have introduced as long as diffusion is neglected. On the other hand, due to the higher central temperature, model (d) has significantly higher 8B and CNO neutrino fluxes. It is essentially the increase of the boron flux which enhances the predicted Chlorine signal. The slight change in the nuclear cross section weakly affects neutrino fluxes and signals: the 7Be and 8B fluxes are reduced by about 5%, S34. Should we use the polynomial parametrization of eq. 3 one would get a further 5% decrease. As a final remark, we want to stress that again our results are in excellent agreement with other recent calculations including diffusion (see table 5), but the prediction of Kovetz & Shaviv (1994) for the 13N and 15O fluxes which are an order of magnitude smaller than those of all other calculations for reasons which are unknown to us 1.

Regarding the comparison with BP95, the small difference in the neutrino production reflects well the small difference in the central temperature, already remarked, and in the adopted values of S34 (see table 6).

1. Acknowledgments

We warmly thank V. Castellini and G. Fiorentini for their advice. F. Ciacio is grateful to CNR for a fellowship. S. Degl’Innocenti and B. Ricci acknowledge the support of the European Union, through the Human Capital & Mobility Program.
