Abstract

Recently, it was proposed to use measurements of $B^0_d(t) \to D^{(*)+}D^{(*)-}$ and $B^0_d \to D_s^{(*)+}D^{(*)-}$ decays to measure the CP phase $\gamma$. In this Letter, we present the extraction of $\gamma$ using this method. We find that $\gamma$ is favored to lie in one of the ranges $[19.4^\circ-80.6^\circ]$ or $[120^\circ-147^\circ]$ at 68% confidence level (the $[120^\circ-147^\circ]$ represents an additional ambiguity for each range). These constraints come principally from the vector–vector final states; the vector–pseudoscalar decays improve the results only slightly. Although, with present data, the constraints disappear for larger confidence levels, this study does demonstrate the feasibility of the method. Strong constraints on $\gamma$ can be obtained with more data.

Recently, two of us (A.D., D.L.) proposed a method for extracting the CP phase $\gamma$ from measurements of $B^0_d(t) \to D^{(*)+}D^{(*)-}$ and $B^0_d \to D_s^{(*)+}D^{(*)-}$ decays [1]. The technique is quite straightforward. Consider the pseudoscalar–pseudoscalar (PP) decay $B^0_d \to D^+D^-$. The amplitude for this decay receives several contributions, described by tree, exchange, $b \to d$ penguin and color-suppressed electroweak penguin diagrams [2]:

$$A^D = (T + E + P_c)V_{cb}^*V_{cd} + P_u V_{ub} V_{ud} + (P_l - P_{EW}^C)V_{tb}^* V_{ld}$$

$$= (T + E + P_c - P_l - P_{EW}^C)V_{cb}^*V_{cd} + (P_u - P_l - P_{EW}^C)V_{ub} V_{ud}$$

$$= A_{et} e^{i\delta_{et}} + A_{ut} e^{i\gamma} e^{i\delta_{ut}}. \tag{1}$$

Here, $A_{ct} = |(T + E + P_e - P_t - P_{EW}^c) V_{cb} V_{cd}|$, $A_{ut} = |(P_e - P_t - P_{EW}^c) V_{ub} V_{ud}|$, $P_t$ is the $\bar{b} \to \bar{d}$ penguin amplitude with an internal $i$-quark, and we have explicitly written out the strong phases $\delta^t$ and $\delta^u$, as well as the weak phase $\gamma$. The second line is obtained by using the unitarity of the CKM matrix, $V_{ub} V_{ud} + V_{cb} V_{cd} + V_{tb} V_{td} = 0$, to eliminate the $V_{tb} V_{td}$ term. The amplitude $\tilde{A}D$ for the decay $B^0_d \to D^+ D^-$ can be obtained from the above by changing the signs of the weak phases.

There are three observables which can be obtained from a time-dependent measurement of this decay: $B$ (the branching ratio), $a_{dir}$ (the direct CP asymmetry) and $a_{indir}$ (the indirect CP asymmetry). In terms of the above parameters, these can be written

$$B \equiv \frac{1}{2} (|A^D|^2 + |\tilde{A}D|^2) = A_{ct}^2 + A_{ut}^2 + 2 A_{ct} A_{ut} \cos \delta \cos \gamma,$$

$$a_{dir} \equiv \frac{1}{2} (|A^D|^2 - |\tilde{A}D|^2) = -2 A_{ct} A_{ut} \sin \delta \sin \gamma,$$

$$a_{indir} \equiv \text{Im}(e^{-2i\beta} A^D \tilde{A}D) = -A_{ct}^2 \sin 2 \beta - 2 A_{ct} A_{ut} \cos \delta \sin(2\beta + \gamma) - A_{ut}^2 \sin(2\beta + 2\gamma).$$

(2)

where $\delta \equiv \delta^u - \delta^t$. Here, $\beta$ is the phase of $B^0_d - \bar{B}^0_d$ mixing, which has been measured in the CP asymmetry in $B^0_d(t) \to J/\psi K_S$ [3]. However, these observables still depend on four unknown theoretical parameters: the two magnitudes $A_{ct}$ and $A_{ut}$, one relative strong phase $\delta$, and the weak phase $\gamma$. We therefore have three observables, but four theoretical unknowns. Thus, in order to obtain weak phase information, it is necessary to add some theoretical input.

This input comes from the decay $B^0_d \to D^+_s D^-$, which receives tree, $\bar{b} \to \bar{s}$ penguin and color-suppressed electroweak penguin contributions [2]:

$$A^D_s = (T' + P'_c) V_{cb} V_{cs} + P' u^s_{ub} V_{us} + (P'_t - P_{EW}^c) V_{ub}^s V_{ts}$$

$$\approx (T' + P'_c - P'_t - P_{EW}^c) V_{cb}^s V_{cs} + (P'_u - P_{EW}^c) V_{ub}^s V_{us}$$

$$\approx (T' + P'_c - P'_t - P_{EW}^c) V_{cb}^s V_{cs} \equiv A'_ct e^{i\delta_{ct}}.\quad (3)$$

(The primes on the amplitudes indicate a $\bar{b} \to \bar{s}$ transition.) Here, the last line arises from the fact that $|V_{ub}^s V_{us}/V_{cb} V_{cs}| \sim 2\%$, so that the piece proportional to $V_{ub}^s V_{us}$ is negligible. The measurement of the total rate for $B^0_d \to D^+_s D^-$ therefore yields $A'_{ct}$. We now make the SU(3) flavour assumption that

$$\Delta \equiv \frac{\sin \theta_c A'_{ct}}{A_{ct}} = \frac{\sin \theta_c |(T' + P'_c - P'_t - P_{EW}^c) V_{cb} V_{cs}|}{|(T + E + P_e - P_t - P_{EW}^c) V_{ub} V_{ud}|} = 1.\quad (4)$$

where $\sin \theta_c$ is the Cabibbo angle. With this assumption, the knowledge of $A'_{ct}$ can be used to give us $A_{ct}$. This in turn means that the three observables in $B^0_d \to D^+_s D^-$ depend on only three theoretical unknowns: $A_{ut}$, $\delta$, and $\gamma$. We can therefore now solve for $\gamma$ (up to discrete ambiguities).

The solution for $\gamma$ is as follows. We introduce a fourth (nonindependent) observable, $a_R$:

$$a_R \equiv \text{Re}(e^{-2i\beta} A^D \tilde{A}D) = B^2 - a_{dir}^2 - a_{indir}^2$$

$$= A_{ct}^2 \cos 2 \beta + 2 A_{ct} A_{ut} \cos \delta \cos(2\beta + \gamma) + A_{ut}^2 \cos(2\beta + 2\gamma).$$

(5)

---

1 This is always the case when one attempts to obtain weak phase information from a decay involving a $\bar{b} \to \bar{d}$ penguin, see [4].
One can obtain $\alpha_R$ from measurements of $B$, $a_{\text{dir}}$ and $a_{\text{indir}}$, up to a sign ambiguity. One can then easily obtain

$$A_{ct}^2 = \frac{\alpha_R \cos(2\beta + 2\gamma) - a_{\text{indir}} \sin(2\beta + 2\gamma) - B}{\cos 2\gamma - 1}. \tag{6}$$

Given the knowledge of $2\beta$, the assumption in Eq. (4) therefore allows us to obtain $\gamma$.

The leading-order theoretical error in this technique is given simply by the $\text{SU}(3)$-breaking ratio of decay constants $f_{D_s}/f_D$ [1]. (There are other errors, such as the neglect of the $E$ amplitude in $A_{ct}$, but these are expected to be smaller.) This ratio has been computed quite precisely on the lattice: $f_{D_s}/f_D = 1.20 \pm 0.06 \pm 0.06$ [5]. With this value, the theoretical error in this method is rather small, so that $\gamma$ can be extracted from measurements of $B_d^0(t) \to D^+ D^-$ and $B_d^0 \to D_s^+ D^-$. Unfortunately, at present data on $B_d^0(t) \to D^+ D^-$ is unavailable, so we cannot apply the above method to this decay. However, the vector–vector (VV) decays $B_d^0(t) \to D^{++} D^{*-}$ and $B_d^0 \to D_s^{++} D^{*-}$ have been measured. The method can be applied in a similar way to these decays, but with some additional complexity as described below. The main theoretical error is given by $f_{D_s}/f_{D_s}$.

A modification of this method can be used when the final state is not self-conjugate, as is the case for vector–pseudoscalar (VP) final states.\footnote{A similar method is described in [6]. However, there is a mistake in that method, due to the fact that the hadronization is different for the decays $B_d^0(t) \to K^* K$ and $B_d^0 \to K K^*$.} Consider the decay $B_d^0 \to D^{++} D^-$. Following Eq. (1), its amplitude can be written

$$A(B_d^0 \to D^{++} D^-) = A_{ct} e^{i\delta_{ct}} + A_{ut} e^{i\gamma} e^{i\delta_{ut}}. \tag{7}$$

(Although we use the same symbols, the amplitudes and strong phases are not the same as those for $B_d^0 \to D^+ D^-$.) Now consider the decay of a $B^0$ meson to the same final state, $B^0 \to D^{++} D^-$. The amplitude for this decay is not simply related to that for $B_d^0 \to D^{++} D^-$ since the hadronization is different: in $B_d^0 \to D^{++} D^-$, the spectator quark is part of the $D^-$, while in $B_d^0 \to D^{++} D^-$ it is contained in the $D^{++}$. We therefore write

$$A(B^0 \to D^{++} D^-) = \tilde{A}_{ct} e^{i\delta_{ct}} + \tilde{A}_{ut} e^{-i\gamma} e^{i\delta_{ut}}. \tag{8}$$

The measurement of $B_d^0(t) \to D^{++} D^-$ still yields three observables, $B$, $a_{\text{dir}}$ and $a_{\text{indir}}$, but now they take more complicated forms. The three observables for the $D^{++} D^-$ final state are:

$$B = \frac{1}{2} \left[ A_{ct}^2 + A_{ut}^2 + 2A_{ct} A_{ct} \cos(\gamma + \delta) + \tilde{A}_{ct}^2 + 2\tilde{A}_{ct} \tilde{A}_{ct} \cos(\gamma - \delta) \right],$$

$$a_{\text{dir}} = \frac{1}{2} \left[ A_{ct}^2 + A_{ut}^2 + 2A_{ct} A_{ct} \cos(\gamma + \delta) - \tilde{A}_{ct}^2 - 2\tilde{A}_{ct} \tilde{A}_{ct} \cos(\gamma - \delta) \right],$$

$$a_{\text{indir}} = A_{ct} \tilde{A}_{ct} \sin(-2\beta - 2\gamma + \delta + \bar{\delta} - \Delta) + A_{ut} \tilde{A}_{ut} \sin(-2\beta - \gamma - \delta - \Delta)$$

$$+ \tilde{A}_{ct} \tilde{A}_{ct} \sin(-2\beta + \gamma + \delta - \Delta) + A_{ut} \tilde{A}_{ut} \sin(-2\beta + \gamma + \delta + \Delta), \tag{9}$$

where $\delta \equiv \beta_{\text{ct}} - \delta_{\text{ct}}$, $\bar{\delta} \equiv \beta_{\text{ut}} - \delta_{\text{ut}}$ and $\Delta \equiv \delta_{ct} - \bar{\delta}_{ct}$.

For the $D^{++} D^-$ final state, the observables are

$$\tilde{B} = \frac{1}{2} \left[ A_{ct}^2 + A_{ut}^2 + 2A_{ct} \tilde{A}_{ct} \cos(\gamma + \bar{\delta}) \tilde{A}_{ct} + \tilde{A}_{ct}^2 + 2\tilde{A}_{ct} \tilde{A}_{ct} \cos(\gamma - \bar{\delta}) \right],$$

$$\tilde{a}_{\text{dir}} = \frac{1}{2} \left[ A_{ct}^2 + A_{ut}^2 + 2A_{ct} \tilde{A}_{ct} \cos(\gamma + \bar{\delta}) - \tilde{A}_{ct}^2 - 2\tilde{A}_{ct} \tilde{A}_{ct} \cos(\gamma - \bar{\delta}) \right],$$

$$\tilde{a}_{\text{indir}} = A_{ct} \tilde{A}_{ct} \sin(-2\beta - 2\gamma + \delta - \bar{\delta} + \Delta) + A_{ut} \tilde{A}_{ut} \sin(-2\beta - \gamma + \delta + \Delta)$$

$$+ \tilde{A}_{ct} \tilde{A}_{ct} \sin(-2\beta - \gamma - \delta + \Delta) + A_{ut} \tilde{A}_{ut} \sin(-2\beta + \gamma - \delta + \Delta). \tag{10}$$
Considering that $\beta$ has been experimentally determined, the 6 observables are written in terms of 8 theoretical unknowns: $A_{\parallel}, A_{\perp}, A_{\text{dir}}, A_{\text{indir}}, \gamma, \delta, \tilde{\delta}$ and $\Delta$. We therefore need 2 assumptions to extract information. These come from using the decays $B_d^0 \rightarrow D_s^{*+}D^-$ and $B_d^0 \rightarrow D_s^0 D^{*-}$. The measurements of the branching ratios for these decays allow us to extract $A_{\parallel}$ and $A_{\perp}$, respectively. With motivation similar to that for the PP mode above, we assume that

$$\frac{\sin \theta_c A_{\parallel}}{A_{\parallel}} = 1, \quad \frac{\sin \theta_c A_{\perp}}{A_{\perp}} = 1.$$  \hspace{0.5cm} (11)

With these assumptions, the measurements of the branching ratios for $B_d^0 \rightarrow D_s^{*+}D^-$ and $B_d^0 \rightarrow D_s^0 D^{*-}$ give us $A_{\parallel}$ and $A_{\perp}$. We now have 6 observables and 6 theoretical unknowns, thus we can solve for $\gamma$ (up to discrete ambiguities). The main theoretical error is the deviation from unity of $\gamma$.

In this Letter we extract $\gamma$ via this method, using BaBar and Belle data on the VV and VP modes [7–13]. We determine the value of $\gamma$ to be in one of the ranges $[19.4^\circ–80.6^\circ]$, $[120^\circ–147^\circ]$, or $[160^\circ–174^\circ]$ at 68% confidence level (C.L.), where the $[120^\circ–147^\circ]$ represents an additional ambiguity for each range. Thus, even though we obtain limits on $\gamma$ at 68% C.L., our main purpose here is to demonstrate the feasibility of the method. With more data, the constraints on $\gamma$ will be correspondingly stronger. Eventually this method can be used to obtain a precision determination of $\gamma$.

We begin with the analysis of vector–vector decays. In order to extract $\gamma$, however, we must make additional assumptions. VV final states come in three transversity states, 0, $\parallel$, and $\perp$. The amplitudes 0 and $\parallel$ are CP-even, while $\perp$ is CP-odd. The data shows that the $D^*\bar{D}^*$ final state is almost entirely CP-even, i.e., the $\perp$ amplitude is negligible [11]. Unfortunately, at present experiments cannot distinguish between the 0 and $\parallel$ amplitudes. This has the following effect. For a single transversity $\sigma$, the three observables in $B_d^0(t) \rightarrow D^{*+}D^-$ can be written similarly to Eq. (2):

$$B_\sigma = A_{\parallel,\sigma}^2 + A_{\perp,\sigma}^2 + 2A_{\parallel,\sigma}A_{\perp,\sigma}\cos \delta_\sigma \cos \gamma,$$

$$a_{\text{dir}}^\sigma = -2A_{\parallel,\sigma}A_{\perp,\sigma}\sin \delta_\sigma \sin \gamma,$$

$$a_{\text{indir}}^\sigma = -2A_{\parallel,\sigma}^2 \sin 2\beta - 2A_{\parallel,\sigma}A_{\perp,\sigma}\cos \delta_\sigma \sin (2\beta + \gamma) - A_{\perp,\sigma}^2 \sin (2\beta + 2\gamma).$$  \hspace{0.5cm} (12)

where $\delta_\sigma \equiv \delta_{\text{dir}}^\sigma - \delta_{\text{indir}}^\sigma$. However, for all three observables, what is measured is the sum of the helicities 0 and $\parallel$:

$$B = \sum_{\sigma=0,\parallel} [A_{\parallel,\sigma}^2 + A_{\perp,\sigma}^2 + 2A_{\parallel,\sigma}A_{\perp,\sigma}\cos \delta_\sigma \cos \gamma],$$

$$a_{\text{dir}} = \sum_{\sigma=0,\parallel} [-2A_{\parallel,\sigma}A_{\perp,\sigma}\sin \delta_\sigma \sin \gamma],$$

$$a_{\text{indir}} = \sum_{\sigma=0,\parallel} [-A_{\parallel,\sigma}^2 \sin 2\beta - 2A_{\parallel,\sigma}A_{\perp,\sigma}\cos \delta_\sigma \sin (2\beta + \gamma) - A_{\perp,\sigma}^2 \sin (2\beta + 2\gamma)].$$  \hspace{0.5cm} (13)

Because the parameters $A_{\parallel}$, $A_{\perp}$ and $\delta$ are different for the two helicities 0 and $\parallel$, there are too many theoretical unknowns to apply the method.

We would like to cast the expressions for the observables in Eq. (13) in the same form as those in Eq. (2). In order to do this, we must relate the parameters for the 0 and $\parallel$ helicities. Specifically, we assume that the strong phases are equal: $\delta_0 = \delta_\parallel \equiv \delta$. We also assume that the amplitudes are proportional to one another (with the same
proportionality constant, \( c \)): \( A_{ct,0} = c A_{ct,|\rangle} \), \( A_{ut,0} = c A_{ut,|\rangle} \). That is, our assumptions are:

\[
\frac{A_{ct,0}}{A_{ct,|\rangle}} = \frac{A_{ut,0}}{A_{ut,|\rangle}}, \quad \delta_0 = \delta_{|\rangle}.
\]

(14)

With these definitions, the observables in Eq. (13) take exactly the same form as Eq. (2), and the method for extracting \( \gamma \) can be applied.

In fact, these assumptions are theoretically reasonable. The amplitudes for \( B_d^0 \to D^* \bar{D}^* \) and \( \bar{B}_d^0 \to \bar{D}^* D^* \) are given by

\[
A_{V\nu,\sigma} = A_{ct,\sigma} e^{i\frac{\delta_{\gamma}}{2}} + A_{ut,\sigma} e^{i\frac{\delta_{\gamma}}{2}} e^{i\frac{\gamma}{2}}, \quad A_{V\nu,\sigma} = A_{ct,\sigma} e^{i\frac{\delta_{\gamma}}{2}} + A_{ut,\sigma} e^{i\frac{\delta_{\gamma}}{2}} e^{-i\frac{\gamma}{2}},
\]

with \( \sigma = 0, |\rangle, \perp \) being the three transversity states. We now define the ratios of amplitudes:

\[
k_{ct} \equiv \frac{A_{ct,0}}{A_{ct,|\rangle}} e^{i(\frac{\delta_{\gamma}}{2} - \frac{\delta_{\gamma'}}{2})}, \quad k_{ut} \equiv \frac{A_{ut,0}}{A_{ut,|\rangle}} e^{i(\frac{\delta_{\gamma}}{2} - \frac{\delta_{\gamma'}}{2})}.
\]

(16)

Our assumptions are equivalent to \( k_{ct} = k_{ut} \), i.e., both amplitudes and phases are equal. Below, we investigate the extent to which these relations hold true.

We note that, in general, we can write any amplitude in terms of factorizable and nonfactorizable pieces:

\[
A_{ct,\sigma} = A_{ct,\sigma}^F e^{i\frac{\gamma}{2}} \left[ 1 + r_\sigma e^{i\rho_\sigma} \right], \quad A_{ut,\sigma} = A_{ut,\sigma}^F e^{i\frac{\gamma}{2}} \left[ 1 + s_\sigma e^{i\lambda_\sigma} \right],
\]

(17)

where we denote the factorizable contributions by an index ‘‘\( F \)’. The quantities \( r_\sigma, \rho_\sigma, s_\sigma \) and \( \lambda_\sigma \) parametrize the ratios of nonfactorizable and factorizable amplitudes.

Consider first only the factorizable contributions. In this case, the ratios of factorizable amplitudes are

\[
k_{ct}^F \equiv \frac{A_{ct,0}^F}{A_{ct,|\rangle}^F} e^{i(\delta_{\gamma} - \delta_{\gamma'})}, \quad k_{ut}^F \equiv \frac{A_{ut,0}^F}{A_{ut,|\rangle}^F} e^{i(\delta_{\gamma} - \delta_{\gamma'})}.
\]

(18)

The factorizable amplitude for the decay \( B_d^0 \to D^* \bar{D}^* \) is given by [17]

\[
A[\bar{B}_d^0 \to D^* \bar{D}^*]^F = \frac{G_F}{\sqrt{2}} X P_{D^*}^F,
\]

(19)

where \( X = X_1 + X_2 \), and

\[
X_1 = V_{cb} V_{us}^* \left[ 2 a_3' + 2 a_4' + a_{10}' - a_3^c - a_4^c \right], \quad X_2 = V_{ub} V_{ud}^* \left[ 2 a_4' + 2 a_3' - a_3^c - a_4^c \right],
\]

\[
P_{D^*}^F = \left[ m_{D^*} f_{D^*} e^{i\phi_{D^*}} |D^*| \bar{c}_G (1 - \gamma_S) b \right| \bar{B_d^0}^*]^F.
\]

(20)

In the above, \( a_j \) are Wilson coefficients. From Eqs. (19) and (20), we can read off the individual factorizable amplitudes:

\[
A_{ct,\sigma} e^{i\delta_{\gamma}^F} = \frac{G_F}{\sqrt{2}} X_1 P_{D^*}^F, \quad A_{ut,\sigma} e^{i\delta_{\gamma}^F} = \frac{G_F}{\sqrt{2}} X_2 P_{D^*}^F.
\]

(21)

However, note that the strong phases come from \( a_j^c, a_j^t \), and appear only in the factors \( X_{1,2} \) in Eq. (20). These factors are independent of transversity. That is, the relative strong phases between the factorizable \( ct \) and \( ut \) amplitudes are independent of the polarization state, leading to \( \text{Arg}(k_{ct}^F) = \text{Arg}(k_{ut}^F) \). Furthermore, the expressions in Eq. (21) above lead to

\[
|k_{ct}^F| = |k_{ut}^F| = \frac{P_{D^*}^0}{P_{D^*}^t}.
\]

(22)

Thus, we have \( k_{ct}^F = k_{ut}^F \), i.e., the factorizable contributions satisfy our assumptions.
We now consider the nonfactorizable contributions. If these pieces are independent of polarization (at least for the $\sigma = 0$, $\parallel$ states), then in Eq. (17) we will have

$$r_0 = r_1 \equiv r, \quad s_0 = s_1 \equiv s, \quad \rho_0 = \rho_1 \equiv \rho, \quad \lambda_0 = \lambda_1 \equiv \lambda.$$  \hspace{1cm} (23)

This leads to $k_{ct} = k_{al}$, so that our assumptions will be satisfied. Our assumptions are therefore invalid only to the extent that the nonfactorizable pieces are transversity-dependent.

In the heavy-quark limit with $m_{b,c} \to \infty$, there is only one universal form factor resulting from the spin symmetry of the theory. This implies that the (factorizable) $P_{D^*}^\sigma$’s in Eq. (21) are proportional for different polarization states. In other words, the various transversity amplitudes are related to one another. It is likely that these relations remain true in the presence of nonfactorizable corrections. This then implies Eq. (23). We therefore expect deviations from Eq. (23) to be suppressed by $O(1/m_{c,b})$. In all, the net correction to our assumptions is $O(1/m_{c,b})$ times the ratio of nonfactorizable and factorizable effects. We expect this to be small, so that the assumptions in Eq. (14) are justified.

Finally, we note that our assumptions can be tested. In the presence of nonfactorizable effects of the form in Eq. (23), Eq. (19) can be rewritten as

$$A(fD_{06}^s \to D^* \bar{D}^*) = \frac{\sqrt{2}}{\sqrt{2}} X_T P_{D^*}^\sigma,$$ \hspace{1cm} (24)

where $X_T = X_{1T} + X_{2T}$, and

$$X_{1T} = V_{tb} V_{cb}^*\left[a_2 + a_4^1 + a_4^{10} - a_4^u - a_4^d\right][1 + re^{i\phi}], \quad X_2 = V_{ub} V_{ud}^*\left[a_1^1 + a_1^{10} - a_1^u - a_1^d\right][1 + s e^{i\lambda}],$$

$$P_{D^*}^\sigma = \left[m_D^* f_{D^*}^{\epsilon_D^\mu} |D^*|^2 \overline{\epsilon}_{\gamma_D^\mu}(1 - \gamma_{D^*})b |B_d^0|^2\right]^\sigma.$$ \hspace{1cm} (25)

As $X_T$ is common to both $\sigma = 0$, $\parallel$ states we find the relative phase between these transversity amplitudes is 0 or $\pi$. This prediction can be checked through an angular analysis of $B \to D^* \bar{D}^*$ decays. Note also that the assumptions in Eq. (14) are not in fact required in the original method of Ref. [1]. Eventually it will be possible to experimentally separate out the $0$ and the $\parallel$ components, making such assumptions unnecessary.

With the assumptions of Eq. (14), we can determine the value of $\gamma$ from the VV decays, using the method above. We use the measurements of the $B \to D^{(*)} \bar{D}^{(*)}$ and $B \to D_S^{(*)} \bar{D}^{(*)}$ branching fractions, measurements of the $B \to D^{(*)} \bar{D}^{(*)}$ CP asymmetries, and the world-average values of $\sin 2\beta$ (0.736 $\pm$ 0.049) [3] and $\sin^2\theta_c$ (0.0482 $\pm$ 0.0010) [18]. We take $2\beta$ to lie in the first quadrant.

We use a toy Monte Carlo (MC) method to determine the confidence intervals for $\gamma$. We consider 500 values for $\gamma$, evenly spaced between 0 and $2\pi$. For each value of $\gamma$ considered, we generate 25000 toy MC experiments, with inputs that span the range of the experimental errors of each quantity. For each experiment, we generate random values of each of the experimental inputs according to Gaussian distributions, with means and sigmas according to the measured central value and total errors on each experimental quantity. We make the assumption that the ratio $f_{D^*}/f_{D^0}$ is equal to $f_{D^*/f_{D^0}} = 1.20 \pm 0.06 \pm 0.06$ [5]. An additional theory error of 10% is included to take into account the assumptions of Eq. (14), as well as smaller errors such as the neglect of the exchange diagram, subdominant SU(3)-breaking terms, etc. We then calculate the resulting values of $A_{ct}$, $a_{dir}$, $a_{indir}$, and $B$, given the generated random values (based on the experimental values). Inputting the quantities $a_{dir}$, $a_{indir}$, and $B$, along with $\beta$ and the value of $\gamma$ that is being considered, into Eq. (6), we obtain a residual value for each experiment, equal to the difference of the left- and right-hand sides of the equation. One thus obtains an ensemble of residual values from the 25000 experiments. A likelihood, as a function of $\gamma$, can be obtained from $\chi^2(\gamma)$, where $\chi^2 \equiv (\mu/\sigma)^2$, in which $\mu$ is the mean of the above ensemble of residual values and $\sigma$ is the usual square root of the variance. The value of $\chi^2(\gamma)$ is then considered to represent a likelihood which is equal to that of a value $\chi$ standard deviations of a Gaussian distribution from the most likely value(s) of $\gamma$. We define the “exclusion level”, as a function of the value of $\gamma$, as follows: the value of $\gamma$ is excluded from a range at a given C.L. if the exclusion level in that range of $\gamma$ values is greater than the given C.L.
The measured exclusion level, as a function of $\gamma$, from a fit to the vector–vector modes ($D^{*+}D^{*-}$ and $D^{*+}_sD^{*-}$). The exclusion level is defined in the text. From the fit, $\gamma$ is favored to lie in one of the ranges $[0.31, 1.50]$ (or $0$ or $\pi$), $[2.02, 2.62]$ (or $0$ or $\pi$), or $[2.72, 3.05]$ (or $0$ or $\pi$) radians at 68% confidence level.

Fig. 2. A “pull distribution” check on the measured confidence levels for the $\gamma$ fit. Values of $\gamma$, as well as the other theoretical parameters $A_1$, $\delta$, and $\beta$, are generated and used to produce values of the experimental inputs to the fit. The fit is then performed, and $(\text{measured value of } \gamma - \text{generated value of } \gamma) / \text{measured uncertainty on } \gamma$ is plotted. The result is consistent with a Gaussian distribution with $\sigma = 1$, implying that uncertainty on the measured value of $\gamma$ is accurately described by the confidence distribution.

Fig. 3. The measured exclusion level, as a function of $\gamma$, from a fit to the vector–pseudoscalar modes $D^{*+}_sD^{*-}$ and $D^{*+}_sD^{*+}$. Unlike the vector–vector modes, with present data we do not obtain useful information on the likely regions of $\gamma$ from these modes alone.

Fig. 4. The measured exclusion level, as a function of $\gamma$, from the combined information from vector–vector and vector–pseudoscalar modes. The combined information implies that $\gamma$ is favored to lie in one of the ranges $[0.34, 1.41]$ (or $0$ or $\pi$), $[2.09, 2.57]$ (or $0$ or $\pi$), or $[2.79, 3.04]$ (or $0$ or $\pi$) radians at 68% confidence level.
ambiguity. We then have the two remaining equations for $a_{\text{indir}}$ and $\tilde{a}_{\text{indir}}$ and two theoretical unknowns, $\gamma$ and $\Delta$.

We now consider 200 values for each of $\gamma$ and $\Delta$, each evenly spaced between 0 and 2$\pi$. For each of the 200 x 200 possible combinations of values of $\gamma$ and $\Delta$, we generate 5000 toy MC experiments, with inputs that span the range of the experimental errors of each quantity.

Similar to the toy Monte Carlo $\gamma$ determination for the VV mode, we generate random values of each of the experimental inputs according to Gaussian distributions, with means and sigmas according to the measured central value and total errors on each experimental quantity. Making the assumption that the experimental inputs according to Gaussian distributions, with means and sigmas according to the measured errors of each quantity.

Finally, we can combine information from the VV and VP modes. The result is shown in Fig. 4. From the combined fit, we see that $\gamma$ is favored to lie in one of the ranges [0.34–1.41](+0 or $\pi$), [2.09–2.57](+0 or $\pi$), or [2.79–3.04](+0 or $\pi$) radians at 68% confidence level. This corresponds to [19.4–80.6](+0 or 180), [120–147](+0 or 180), or [160–174](±0 or 180). Comparing Figs. 1 and 4, we see that the favored ranges of $\gamma$ are slightly more constrained with the VP data. Thus, although the VP data does not by itself constrain $\gamma$, its inclusion in the combined fit does have an effect.

To summarize, we have presented the extraction of $\gamma$ using measurements of $B^0_\text{u}(t)\rightarrow D^{(*)}+\bar{D}^{(*)}-$ and $B^0_\text{u}\rightarrow D^{(*)}+\bar{D}^{(*)}-$ decays [1]. We find that $\gamma$ is favored to lie in one of the ranges [19.4–80.6](+0 or 180), [120–147](+0 or 180), or [160–174](±0 or 180) at 68% confidence level (the (+0 or 180) represents an additional ambiguity for each range). The first of these ranges is that favored by fits to the unitarity triangle, assuming the standard model. The ranges come primarily from data on vector–vector decays, although the vector–pseudoscalar decays do improve the constraints slightly. Note that, if we consider a larger confidence level, there are no constraints on $\gamma$ at present. However, this study demonstrates the feasibility of the method—with more data, we will be able to obtain strong constraints on $\gamma$.
