Three-Point Bending of Heat-Treatable Aluminum Alloys: Influence of Microstructure and Texture on Bendability and Fracture Behavior

IDA WESTERMANN, KNUT ERIK SNILSBERG, ZEINAB SHARIFI, ODD STURE HOPPERSTAD, KNUT MARTHINSEN, and BJØRN HOLMEDAL

Three-point bending tests of extruded aluminum alloys showed lower bendability when the bending axis is aligned with the extrusion direction compared to the transverse direction. In the present work, three different microstructures of a commercial AA7108 aluminum alloy were studied with respect to mechanical properties, texture, constituent particles, and crack propagation. The three different microstructures were an as-cast and homogenized material, a fibrous extruded material, and a cold rolled and recrystallized material. While the mechanical properties in tension are more or less the same for the three materials, the bendability is strongly dependent on the microstructure and the global alignment of constituent particles. The as-cast and homogenized material shows poor bendability due to large grains and constituent particles on the grain boundaries, which leads to decohesion and premature failure. The response of both the fibrous and the recrystallized materials depends on the direction of the bending axis. A strong fiber texture is found to influence the bendability by initiation of shear bands. The crucial fracture mechanism, however, seems to be the global alignment of constituent particles, which is inherited from the deformation process.

1. INTRODUCTION

ALUMINUM alloys in the form of rolled sheets and extruded profiles intended for use in the automotive industry should possess an appropriate combination of strength and ductility. Sheets or profiles are typically formed into final shapes such as body panels or bumper beams by cold deformation. Hence, the bendability of the material is of great importance in fabrication as well as in use, where the ductility is required for optimal energy absorption. Uniaxial tensile testing is often used to determine the mechanical properties of metals. However, this type of test does not always give a good description of the deformation mode experienced by a component. In this case, the three-point bending test is a suitable method for describing the mechanical properties. The bendability is defined as the ratio between the minimum bending radius and the thickness of the test specimen without fracture occurring.\cite{1-4} In 1960, Datsko and Yang\cite{1} came up with a simple relationship between bendability and the reduction in area obtained by tensile testing. This empirical relationship, however, does not include any of the underlying microstructural mechanisms. Several phenomena influence the bendability, e.g., hardening behavior, constituent particles, shear band formation, microstructure, and texture/anisotropy.

Experimental findings, e.g., References 5 through 7, indicate that the presence of constituent particles influences the bendability of aluminum alloys. What part the particles play in the damage of the material, however, is still uncertain. Sarkar et al.\cite{7,8} in agreement with Datsko and Yang,\cite{1} have shown that an increasing amount of constituent iron-rich particles not only influences the bendability of an alloy, but also the tensile ductility. Ragab and Saleh\cite{9} and Bettaieb et al.\cite{10,11,12} took into account void growth and coalescence in modeling of bendability. Constituent particles in metals are found to be natural nucleation sites for microvoids.\cite{6} Dao and Li\cite{12} and Wilkinson et al.,\cite{13} however, suggest that the particles also affect the formation of shear bands during bending, which essentially leads to fracture. Shear localization plays a major role in fracture initiation.\cite{12,14-17,18} In anisotropic materials such as rolled and extruded metals, the texture is found to affect the shear band formation as well. Kuroda and Tvergaard,\cite{14} in their finite element analyses, systematically studied the effect of different texture components with respect to strain localization.

Experiments on extruded aluminum profiles showed better bendability when the bending axis (BA) was parallel to the extrusion direction, than when it is perpendicular to it, for both recrystallized and fibrous grain morphologies.\cite{18} The aim of this experimental...
study is to characterize the bendability of a heat-treatable AA7108 aluminum alloy and compare it to results from tensile testing, for verification of already existing numerical results. By manipulation of the microstructure, the effect of grain morphology, texture, and distribution of constituent particles on bendability and fracture mechanisms is investigated.

II. MATERIAL AND EXPERIMENTAL PROCEDURE

A commercial AA7108 aluminum alloy was provided by Hydro Aluminium Structures Raufoss AS in two initial conditions, namely, as extruded profiles and as-cast and homogenized ingots. In addition to the two initial conditions, rolling ingots were made from the as-cast and homogenized material. These were heat treated at 793 K (520 °C) for 30 minutes, quenched, and cold rolled to a strain of 1.39. The extruded and the as-cast and homogenized materials were solution heat treated at 753 K (480 °C) for 20 minutes, while the rolled material was solution heat treated at 793 K (520 °C) for 20 minutes to obtain a recrystallized microstructure. To ease the reading, the three different materials will in the following be referred to as the as-cast material, the extruded material, and the recrystallized material, meaning the as-cast and homogenized material, the fibrous extruded material, and the rolled and recrystallized material, respectively. In Figure 1, the microstructures of the three materials are presented. The as-cast material has equiaxed grains with a grain size of ~155 μm. The recrystallized material contains ellipsoidal grains, ~14 μm in the short direction normal to the rolling direction (denoted ND) and ~24 μm in the rolling direction. The extruded material has a fibrous microstructure with grains up to several centimeters in the extrusion direction, but only 7 μm between the high-angle boundaries in the normal direction. For all the conditions, the solution heat treatment was followed by storage at room temperature for 24 hours and a two-step artificial aging, the first step being holding at 373 K (100 °C) for 5 hours followed by 423 K (150 °C) for varying amounts of time. Based on the aging curves in Figure 2, two tempers were chosen, at 5 and 24 hours, i.e., one underaged/close to peak aged and one overaged.

For comparison of the crystallographic texture of the extruded and the recrystallized material, texture data were collected by use of standard X-ray diffraction in a Siemens D5000 diffractometer (Bruker-AXS, Delft, Netherlands) for the two conditions. Orientation distribution functions (ODFs) were calculated assuming orthotropic sample geometry. A random crystallographic texture was assumed for the as-cast material, in accordance with general experience. Due to the large
grain size, the numbers of grains in a specimen are insufficient for a statistically reliable texture analysis and, therefore, is not performed.

To further characterize the anisotropy of the extruded and recrystallized materials, respectively, standard tensile specimens were made in 0, 45, and 90 deg with respect to the deformation direction (extrusion direction or rolling direction). Before testing, the tensile specimens were heat treated to the 5- and 24-hour tempers. Tensile testing was carried out at a constant nominal strain rate of 0.01 s\(^{-1}\). The reduction in area after fracture was measured by use of image processing on the cross-sectional projection of the fracture surface.

Specimens for three-point bending were machined from all three materials. The dimensions were 60 mm \(\times\) 60 mm \(\times\) 3.17 \(\pm\) 0.04 mm for the extruded material and 50 mm \(\times\) 50 mm \(\times\) 2.96 \(\pm\) 0.09 mm for the recrystallized and as-cast materials. The bending specimens were then heat treated to the 5- and 24-hour temper. Three-point plane-strain bending tests were performed with the BA along either the deformation direction (ED is used throughout the rest of the article) or the transverse direction (TD) for both the extruded and the recrystallized samples. In addition the extruded material was tested in the 45 deg direction. Due to geometrical restrictions, this was not possible with the recrystallized material. For the as-cast material, the BA was chosen arbitrarily, independent of direction. The tests were performed in a Zwick testing machine (Figure 3) according to guidelines proposed by Daimler Chrysler.\(^\text{[19]}\) A constant vertical speed of 20 mm/min was chosen, and the roll gap was 2 times the specimen thickness plus 0.2 mm. Force was logged as a function of vertical displacement, and the test was stopped when the force-displacement curve showed a significant drop. Figure 4 illustrates the bending stresses and their direction relative to the BA in a three-point bending test. The figure schematically shows how the test specimen experiences tension on the lower surface and compression on the upper surface (against the knife). These stresses act perpendicular to the BA. This means that when comparing anisotropy in bending and in tension, the BA should be perpendicular to the direction of the tensile specimen to obtain tension in the same direction. However, it should be noted that the stress states in bending and uniaxial tension are different. In bending, there are also stresses parallel to the BA. These are compressive on the upper surface and tensile on the lower surface (cf. Figure 4).

The bending angle was measured manually afterwards according to standard procedures,\(^\text{[19]}\) and the bending radius was determined by use of macrographs and image processing. A cut was made perpendicular to the BA,
allowing the microstructure and the fracture propagation to be examined by light optical microscopy.

After three-point bending, the deformed samples of the as-cast and the recrystallized materials were further bent until failure and the fracture surfaces were investigated in a Zeiss Gemini Supra 55 VP FESEM (Carl Zeiss International, Germany). To investigate whether the presence of constituent particles influences the bendability, the distribution of primary particles was also investigated in the ED-ND plane and the TD-ND plane of the recrystallized material in SEM.

### III. RESULTS

The macrotextures of the extruded and the recrystallized materials are presented in Figure 5 in the form of ODFs. The extruded material in Figure 5(a) shows a typical deformation texture with a strong $\beta$ fiber running from the Bs orientation over the S orientation to the Cu orientation. Intensities of the cube orientation are also observed in the 0 deg section. The macrotexture of the recrystallized material in Figure 5(b) reveals a very weak retained deformation texture from cold rolling (note

![Fig. 5—ODFs obtained for (a) the extruded material and (b) the rolled and recrystallized material.](image-url)
that there is a factor 10 in difference between the maximum levels in the two ODFs, with a maximum of only 3.2 in the latter).

The true stress-strain curves for the extruded and recrystallized materials are presented in Figure 6. Regarding the extruded material in Figure 6(a), the strength and uniform elongation of the underaged samples, in general, are higher than for the overaged ones in the respective directions. The strength is at the same level with the tensile direction aligned 0 and 90 deg to the extrusion direction, whereas the strength in the 45 deg direction is significantly lower. The uniform elongation, however, is lower in the 90 deg direction. This holds for both tempers. From Figure 6(b), less differences are observed for the recrystallized material, both with respect to tempers and to tensile directions. Also, the recrystallized material, the uniform elongation is lower for the underaged temper. For comparison, the true stress-strain curves are plotted for all three materials of the 5-hour temper in Figure 7. Only the directions with the extreme behaviors were included for the two deformed conditions, i.e., the 0 and 45 deg directions. The extruded material represents the two extremes with the 45 deg as the weakest and the 0 deg as the strongest direction. The as-cast and the recrystallized materials lie in between. The recrystallized material is

| Recrystallized| 24 h   | 0                                                   | 380             | 438         | 0.078        | 22.2      |
|              |        | 45                                                  | 372             | 416         | 0.084        | 31.9      |
|              |        | 90                                                  | 392             | 429         | 0.084        | 23.8      |
somewhat stronger than the as-cast one. All materials show similar work-hardening behaviors. In Table I, the 0.2 pct offset yield strength \( (R_{0.2}) \), ultimate tensile strength \( (R_m) \), uniform strain \( (\varepsilon_u) \), and reduction in area after fracture \( (q) \) are listed for the three directions of the extruded and recrystallized material, as well as for the as-cast 5-hour temper. The values for yield and ultimate tensile strength reflect the observations in the true stress-strain curves. The reduction in area is used as a measure for the ductility in tension. The extruded material experiences

Based on the force-displacement curves from the
three-point bend ing tests, the force \( F \) was normal ized
with the wid ths \( w \), thickne sses \( t \) of the specim ens, and
the distance between the roll ers \( L_0 \). The normalized
force is shown vs the normalized vertical displace ment
\( \Delta /t \) in Figure 8 for the different mate rials. Figures 8(a),
(c), and (e) show the 5-hour temper and (b), (d), and (f)
the 24-hour temper. Both tempers show the same trend
with respect to the different mate rials. The as-cast
material is lowest in normalized force and, in particular,
low in vertical displacement. Both direc tions of the
recystallized material experience the same magnitude of
normalized force. However, when the BA is aligned
90 deg with respect to the rolling direc tion, a much
higher vertical displacement is achieved. The extruded
material, on the other hand, shows a differ ence in both
normalized force and displacement, depending on the
direction of the BA. When the BA is along the extrusion
direction (0 deg), the normalized force is higher, but the
displacement is lower compared to the samples with the
BA oriented along the TD. The normalized force is at
the same level for the samples aligned 45 deg to the
extrusion direc tion compared to those aligned along the
extrusion direc tion. The obtainable displacement, how-
ever, is higher in 45 deg than in the other two direc tions.

The test was stop ped as soon as a sig nif icant drop in
force was observed, as reflected by the curves. Sub-
sequent to unloading, the bending angles were measured
for all the materials and are listed in Table II along with
a typical value of the \( r/t \) ratio. The as-cast mate rial is
independent of direction and shows the poorest bend-
dability for both tempers compared to the other mate rials.
Best performance is observed for the recystallized
material, while the bending angle of the extruded
material is somewhat lower. When comparing the
difference between the two tempers, the averaged
24-hour temper has a higher bending angle than the
5-hour temper for the respective direc tions of all the
materials. For the extruded material, the best results are
achieved with the BA aligned 45 deg to the extrusion
direction. Comparing the results only with the BA

Table II. Measured Bending Angles after Three-Point Bending and Typical Values of the Bendability for All Three Materials

Fig. 9—Micrographs of the deformed as-cast material: (a) the 5 h temper and (b) the 24 h temper.

large differences dependent on direction. In the 45 deg
direction, the reduction in area is more than twice that
observed in 0 and 90 deg. The ductility is slightly higher for
the overaged 24-hour temper for both the extruded and the
recystallized materials. For the recystallized material, the
reduction in area is more consistent for the three direc-
tions, but still a little higher in 45 deg.
aligned along the extrusion direction or the TD (excluding the 45 deg direction), the highest angles and best bendability are obtained with the BA in the TD. This applies to both tempers of the extruded and the recrystallized materials.

The crack propagation in the materials deformed by three-point bending was investigated by use of light-optical microscopy. A through-thickness overview of the crack propagation in the two as-cast tempers is presented in Figure 9. Both the 5-hour temper in (a) and the 24-hour temper in (b) show a combination of intercrystalline and transcrysalline fracture modes.

In the case where the materials were predeformed and heat treated before aging, i.e., the extruded and the cold rolled and recrystallized materials, three-point bending was carried out with the BA along both the ED and TD. Figure 10 shows an overview of the samples deformed with the BA along ED. Figures 10(a) and (b) show the 5-hour tempers of the extruded and recrystallized material, respectively. The 24-hour tempers of the extruded and recrystallized materials, in turn, are illustrated in (c) and (d). In all the cases, the fracture is initiated as a shear fracture on the tension side of the samples, and as the crack propagates, the mode turns into a mixture of intercrystalline and transcrysalline crack growth, which is most pronounced for the 5-hour temper. On the compression side of both the extruded tempers in (a) and (c), intense shear band formation is observed symmetrically on both sides of the BA. This phenomenon is not observed for the recrystallized samples. In the case where the BA is aligned along the TD (Figure 11), the crack propagates from the tension side of the sample as a transcrysalline shear fracture. This holds independent of microstructure and temper. While the crack front is intense and narrow for the 5-hour temper of the extruded material in (a), the 24-hour temper has a somewhat broader crack tip (Figure 11(c)).

The deformed samples of the as-cast and recrystallized materials were further bent until failure, and the fracture surfaces were investigated in SEM. The SEM images of the as-cast material are shown in Figures 12(b) and (d) along with the corresponding optical micrographs in (a) and (c) for the 5- and 24-hour tempers, respectively. The optical micrograph of the 5-hour temper in (a) shows a narrow and very “clean” crack compared to the broader crack in the 24-hour temper in (c) (also Figure 9). The transcrysalline parts of the crack seem to occur where there is a high density of constituent particles. In the 5-hour sample, small intercrystalline secondary cracks perpendicular to the crack front are observed in the micrograph. These are clearly distinguished in the SEM image in Figure 12(b). The fracture surface of the 24-hour temper in Figure 12(d) shows more dimples than the 5-hour temper. Pores on the ridge indicated by arrows in (d) are caused by alignment of primary particles in the cast structure.
In Figure 13, two fracture types are shown for the recrystallized 5-hour temper. In (a) and (b), the BA was aligned along the ED. The fracture shows a characteristic zigzag shape, and the fracture surface reveals stringers of primary particles along the extrusion direction (indicated by small arrows) in (b). In (c) and (d), the BA was aligned along the TD, which gives a 45 deg shear fracture (Figure 13(c)). The fracture surface in (d), at the edge of the sample, shows transcrysalline cleavage. Note that there is a difference in magnification between (b) and (d).

The particle distribution in the ED-ND and TD-ND planes for the recrystallized material is illustrated in Figures 14(a) and (b), respectively. The rolling process before recrystallization caused the primary particles to line up like beads on a string along the rolling direction (ED), as pointed out by arrows in Figure 14(a). In the TD-ND plane in Figure 14(b), however, the particles are more randomly distributed.

IV. DISCUSSION

From the tensile data, it is interesting to find that the strength of all three materials lies within the window defined by the two extremes of the extruded material for the given tempers, i.e., a deviation less than 15 pct from the maximum strength. The uniform strain varies little between the three materials (cf. Table I), though it is a little lower for the overaged conditions. For the extruded material, there is a slight decrease in uniform strain from the 0 to the 90 deg direction. This is, however, not a consistent observation for the recrystallized tempers. There is, in other words, no clear correlation between uniform strain and bendability. Regarding $q$ (reduction in cross-sectional area after fracture), there is a much larger difference between the materials. However, the trend in most of the cases contradicts the bendability, except for the recrystallized underaged material in the 90 deg direction. The observed anisotropic behavior in bending, therefore, must be explained by other influencing factors. Figure 15 illustrates the bendability ($r/t$), plotted as a function of the reduction in area, $q$. The given direction here refers to the tensile direction. The full lines are relationships suggested by Datsko and Yang.\cite{1} In most cases, the bendability observed in this work is better than the predictions by Datsko and Yang (the lower the $r/t$ ratio, the better the bendability). Except for the as-cast material, there is no large scattering in the $r/t$ ratios. The extruded material, however, does show a much larger spread in the $q$ value depending on the tensile direction.

The as-cast material shows the poorest behavior in three-point bending. The investigations of the crack propagation (Figure 9) reveal a different pattern
Compared to the two other materials, in the as-cast material, the crack follows a path along the highest density of primary particles, i.e., along grain boundaries and in the dendritic as-cast structure in the grain interior. Compared to the recrystallized material, the grain size in the as-cast material is more than 10 times larger, and it is hard to obtain compatibility between the grains during three-point bending. The reason for the poor bendability seen for the as-cast material, therefore, is most likely due to the large grains and the primary particles in the as-cast and homogenized structure.

In general, the overaged 24-hour temper reveals better bendability for all three materials. In the 24-hour temper of the as-cast and the extruded materials, a broader plastic zone is observed around the crack front (Figures 9(b) and 11(c)). Hence, the plastic zone covers a much larger area, leading to a larger dissipation of energy and, thus, a better bendability. However, this is not seen to the same extent in the recrystallized material in Figure 11(d). Dumont et al.\textsuperscript{[20,21]} discussed the factors that influence the fracture resistance, i.e., yield stress inhomogeneity, strain hardening, and grain boundary precipitation. Here, yield stress inhomogeneity means the differences in yield stress between the grain interior and precipitate-free zones along the grain boundary. Their investigations covered the notch resistance of two 7xxx alloys subjected to Kahn tear testing. Even though the specimen in a three-point bending test experiences a less complex deformation mode, the same deductions regarding fracture resistance should be applicable in this case. The recrystallized and the extruded overaged materials are similar in yield stress and strain hardening (cf. Figure 6 and Table I). No large difference in grain boundary precipitation is expected between the underaged and overaged tempers. The reason for the large plastic zone in the overaged 24-hour materials, therefore, should be found in the interaction between dislocations and the non-shearable precipitates in a soft depleted matrix. However, further investigations are necessary to gain more knowledge about this interaction.

Strain localization in the form of shear band formation is the major failure initiation mechanism in three-point bending of the predeformed materials. In plane-strain bending, the material is already in a favorable stress state for shear band formation compared to uniaxial tension. Both Dao and Li\textsuperscript{[12]} and Sarkar et al.\textsuperscript{[7]} have concluded that roughening and grooves at the surface, typically at grain corners, work as initiation spots for the shear band formation. Dao and Li\textsuperscript{[12]} concluded that a deformation texture leads to an increased roughening of the surface compared to a random texture. Kuroda and Tvergaard,\textsuperscript{[14]} in their simulations, have systematically investigated how the different texture components influence the surface roughening and shear band formation. Especially, the texture components Bs, Goss, and S, i.e., typical
deformation texture components, seem to promote the formation of shear bands independent of the direction of BA. This was found not only on the tension side, but also on the compression side of the samples in three-point bending, especially pronounced with the BA aligned with the rolling direction. This is consistent with the observation in Figures 10(a) and (c), where intense shear bands are seen on the compression side of the extruded material, where we have a strong deformation texture (cf. Figure 5(a)). This phenomenon is not observed for the recrystallized material, where the observed texture is very weak and closer to a random texture. In the simulations by Kuroda and Tvergaard,\textsuperscript{[14]} a random texture revealed a much more homogenous
the shear bands are formed, most of the deformation is localized in the bands; i.e., in this case, ductile fracture occurs directly in the bands.

V. CONCLUSIONS

Three-point plane-strain bending tests were carried out on two tempers of an AA7108 alloy with three different microstructures: as-cast and homogenized material, fibrous extruded material, and cold rolled and recrystallized material. Despite a similar strength in tension, the three materials reveal a large variation in bendability. The as-cast and homogenized material performs extremely poorly in three-point bending. This is most probably due to the nature of the as-cast microstructure, with large grains and constituent particles aligned on the grain boundaries and in the dendritic as-cast structure. This causes a combination of intercrystalline and transcrystalline fracture along the path with the highest density of particles. Both of the two preformed materials show anisotropic behavior in three-point bending, with a better bendability when the BA is aligned with the TD. The extruded material with a strong fiber texture shows an anisotropic behavior both in tension and bending tests with respect to the normalized force. The cold rolled and recrystallized material with a very weak texture, on the other hand, exhibits a nearly isotropic behavior. Shear band formation was found to be the major failure initiation mechanism and is influenced by texture. Investigations of the crack propagation, however, show that the reason for the difference in bendability should be found in the alignment of primary particles along the deformation direction.
