Key words binaries: general – stars: early-type – stars: fundamental parameters – stars: statistics

Massive stars are of interest as progenitors of supernovae, i.e. neutron stars and black holes, which can be sources of gravitational waves. Recent population synthesis models can predict neutron star and gravitational wave observations but deal with a fixed supernova rate or an assumed initial mass function for the population of massive stars. Here we investigate those massive stars, which are supernova progenitors, i.e. with O- and early B-type stars, and also all supergiants within 3 kpc. We restrict our sample to those massive stars detected both in 2MASS and observed by Hipparcos, i.e. only those stars with parallax and precise photometry. To determine the luminosities we calculated the extinctions from published multi-colour photometry, spectral types, luminosity class, all corrected for multiplicity and recently revised Hipparcos distances. We use luminosities and temperatures to estimate the masses and ages of these stars using different models from different authors. Having estimated the luminosities and the masses of all our stars within 3 kpc, in particular for all O- and early B-type stars, we have determined the median and mean luminosities for all spectral types for luminosity classes I, III, and V. Our luminosity values for supergiants deviate from earlier results: Previous work generally overestimates distances and luminosities compared to our data, this is likely due to Hipparcos parallaxes (generally more accurate and larger than previous ground-based data) and the fact that many massive stars have recently been resolved into multiples of lower masses and luminosities. From luminosities and effective temperatures we derived masses and ages using mass tracks and isochrones from different authors. From masses and ages we estimated lifetimes and derived a lower limit for the supernova rate of \( \approx 20 \) events/Myr averaged over the next 10 Myr within 600 pc from the sun. These data are then used to search for areas in the sky with higher likelihood for a supernova or gravitational wave event (like OB associations).

1 Introduction

To estimate the ages and masses of stars, one almost always needs their luminosities and temperatures to compare their location in the H-R diagram with theoretical isochrones and tracks. Only in a few rare cases, other mass (or age) estimates are possible, e.g. in eclipsing double-lined binaries. Luminosity, mass, and age are very important parameters to study and understand the formation of stars. In particular for massive stars, as studied here, the formation mechanism is still a matter of debate, either accretion from massive disks and/or coagulation of lower- mass stars (see e.g. Zinnecker & Yorke 2007, for a recent review).

For a lot of studies, typical mean luminosities and masses of stars of a particular spectral type and luminosity class (LC) are necessary, e.g. spectro-photometric distance or mass-luminosity relation.

Here, we use Hipparcos (Perryman et al. 1997) parallaxes to re-estimate the luminosities of all massive stars within 3 kpc, for which both new Hipparcos (van Leeuwen 2007a,b) and 2MASS (Cutri 2003) data are available. We use Hipparcos/Simbad \((B V)\) and 2MASS \((J H K)\) photometry together with the known spectral type and luminosity class to estimate the extinction. From these data, we also estimate all luminosities and masses.

We restrict our sample to those stars which are assumed to be progenitors to supernova and/or neutron stars. Data as determined in our study are also necessary ingredients to population synthesis models to explain current neutron stars observations and to predict future gravitational wave detections.

2 The sample

We compile a list of all known massive stars, which are supposed to explode as supernova (SN), i.e. for LC V and IV spectral types equal or earlier than B4, for LC III equal or earlier than B9 and for LC I and II all spectral types (massive red giants and supergiants), all within a distance to the sun of 3 kpc. This distance is chosen, so that we are complete for stars earlier than B3V with \( A_V \leq 2.5 \) mag (limit for Hipparcos with at least 1 mas accuracy) and for comparison with the population synthesis in Popov et al. (2005). This list contains 16 304 stars selected from Simbad, 3042 of them have revised Hipparcos parallaxes (van Leeuwen

Table 1  Input data of the first ten stars sorted by ascending relative error of the parallaxes (new reduced Hipparcos parallaxes from van Leeuwen 2007, corrected using Eq. (21) in Smith & Eichhorn 1996). B and V band magnitudes and spectral types are obtained from the Simbad data base (Hipparcos), JHK magnitudes and their errors derived from the 2MASS catalogue. If the spectral type is listed in Pourbaix et al. (2007) we give this value. For conversion from spectral type and luminosity class to temperature see Sect. 4. The complete sample will be available at the CDS/VizieR data base in electronic form.

| Hip     | B   | V   | J   | H   | K   | π      | Sp. Type | T_eff |

2007) and 2713 of those Hipparcos stars also have JHK magnitudes in 2MASS (Two Micron All Sky Survey, Cutri 2003), searching by the Hipparcos identifier. Some stars (for example Hip 22392 or Hip 23527) from the Magellanic Clouds accidently have parallaxes ≥0.33 mas listed in Hipparcos and/or in van Leeuwen (2007) and would be in this sample. Therefore we cut out circular regions with a radius of seven degrees for the Large Magellanic Cloud and 3.5 degrees for the Small Magellanic Cloud. Finally 2668 stars from the original 2713 stars (Hipparcos and 2MASS) are left in our list.

We have checked all stars for information about multiplicity in Simbad and catalogues about spectroscopic and eclipsing binaries, namely the binary catalogues from Pourbaix et al. (2007) and Docobo & Andrade (2006) (both for spectroscopic binaries) and from Bondarenko & Perevozkina (1996) and Brancewicz & Dworak (1980)\(^1\), Surkova & Svechnikov (2004) and Perevozkina (1999) listing eclipsing binaries. For 302 stars, there is not enough data available on the companion(s) to estimate parameters like luminosity correctly for all components, so that we omit them from our list. Our list then contains 2323 (247 multiples + 2076 singles, after checking for redundancy) stellar systems, with multiples counted once, with a total of 2398 stars having all parameters for the mass calculation.

There are 247 spectroscopic or eclipsing systems in our list from the papers mentioned above. All those papers (expect Pourbaix et al. 2007) list dynamical masses, which are better than our model-dependent masses, so that we will use the published dynamical masses; for the stars in Pourbaix et al. (2007), good photometry is given for all known components, so that we can estimate the masses for all components from the published data (as we do for all other stars in our list). The input data are listed in Table 1.

\(^1\) For Hip 108317 with an orbit period of ~20 yr, Brancewicz & Dworak (1980) did not obtain dynamical masses, so that we obtain and use own masses for both components from public data.

3 Colours and extinction

The 2MASS magnitudes are well measured, with a median of the relative error of 0.34% for J magnitudes. More than 96% of all J magnitudes have errors lower than 10%. The errors of the H and K magnitudes are comparable to those from J (Cutri 2003). We use a general error of 1% for the B and V magnitudes (Simbad and Hipparcos). The calculation of the bolometric corrections from the spectral types and the extinction (\(A_V\)) due to the interstellar medium follows the procedure in Hohle et al. (2009) using the bolometric corrections and the intrinsic colour indices from Bessell et al. (1998), Kenyon & Hartmann (1995), and Schmidt-Kaler (1982). For the spectral types M4–6, we cannot use Bessell et al. (1998), which goes down to 3500 K only, so that we use only Kenyon & Hartmann (1995) and Schmidt-Kaler (1982) for these stars.

We calculated the \(A_V\) values from single stars calculated from \((B - V)\) using the intrinsic colours from different authors. Errors refer to 1\(\sigma\).
to the one-to-one relation \( Y(x) = Ax + a \) with the results listed in Table 2. We only use those colours for our calculations, which are bold faced in Table 2. The criteria for selection is the following: If one linear fit is not consistent to \( \geq 2 \) others, we do not use it, for example \((B - V)_{0}\) from Kenyon & Hartmann (1995). We treat a linear fit as consistent to another one, if \( A = 1 \pm 0.1 \) considering the scattering \( dA \) and if \( a = 0 \pm 0.1 \)mag considering \( da \). With this criteria we select \((V - K)_{0}\), \((V - J)_{0}\) and \((V - H)_{0}\) from Kenyon & Hartmann (1995)/Schmidt-Kaler (1982). One exception is \((V - K)_{0}\) from Bessell et al. (1998). Although it is not consistent to more than two linear fits from Bessell et al. (1998), it is consistent to \((V - K)_{0}\) from Kenyon & Hartmann (1995), whose consistency is already shown.

Generally, the extinctions derived from the different authors and different magnitudes are well in agreement (see also Figs. 1–2). The final \( A_{V} \) value for each star is calculated from the mean of the \( A_{V} \) values from the four colours marked bold in Table 2. 109 stars have mean \( A_{V} \) values below zero (probably due to variability and non-simultaneous photometry) but all of them are consistent to zero within their 1\( \sigma \) error. We set the \( A_{V} \) values for these 109 stars to zero for all further calculations.

For the resolved 247 binary systems the various catalogues list spectral types and visual magnitudes for both components. We estimated the \( BJHK \) magnitudes of the components from the \( BVJHK \) magnitudes and the spectral types of the unresolved system listed in 2MASS and/or Simbad using the resolved \( V \) magnitudes and spectral types given in the catalogues of both components with a procedure as in Hohle et al. (2009).
Fig. 6  Median bolometric luminosities after the application of the Smith & Eichhorn (1996) correction (left panels) for their parallax (dots, at least five stars per spectral sub-type) and the median luminosities of the stars from the catalogue of Pourbaix et al. (2007) (squares, at least three stars per spectral sub-type), the dotted lines show the linear interpolation between the two subsamples compared to the standard bolometric luminosities from Schmidt-Kaler (1982) as solid lines. The error bars give the standard deviations (in some cases the error bars are smaller than the symbol size). Right panels: same without Smith & Eichhorn (1996) parallax correction. Schmidt-Kaler (1982) overestimates the luminosities due to ground based parallaxes and unresolved multiples.
Fig. 7  Same as in Fig. 6, but only for those stars within 600 pc. Note that in this case the number of supergiants per spectral sub-type is too low for reliable statistics.
Table 2  Results of the fits for the one-to-one relation \( Y(x) = Ax + a \) of the \( A_V \) values for single stars using \( BVJHK \) magnitudes and intrinsic colours from Bessell et al. (1998, B98) and a combination from Kenyon & Hartmann (1995) and Schmidt-Kaler (1982) (KH95SK82).

|         | B98   | A   | 95% Conf. Intervall of A | \( a \) | 95% Conf. Intervall of \( a \) |
|---------|-------|-----|--------------------------|-------|--------------------------|
| \( B - V \) vs. \( V - K \) | 1.040 | (1.016, 1.064) | 0.190 | (0.167, 0.213) |
| \( B - V \) vs. \( J - H \) | 1.175 | (1.126, 1.225) | -0.195 | (-0.243, -0.147) |
| \( B - V \) vs. \( J - K \) | 1.094 | (1.048, 1.139) | 0.240 | (0.196, 0.284) |
| \( V - K \) vs. \( J - H \) | 1.134 | (1.099, 1.169) | -0.414 | (-0.456, -0.372) |
| \( V - K \) vs. \( J - K \) | 1.097 | (1.068, 1.126) | 0.002 | (-0.034, 0.037) |
| \( J - H \) vs. \( J - K \) | 0.847 | (0.832, 0.862) | 0.470 | (0.449, 0.490) |

Table 3  List of the first ten from 2323 stars (see also Table 1). We derived the luminosities from the corrected (Smith & Eichhorn 1996) parallaxes. From luminosities and effective temperatures we calculated the masses (using the models below and taking the errors of the luminosities into account) with medians and standard deviation. The complete table will be available at the CDS/VizieR data base in electronic form.

| Hip  | \( L \) | \[ L_\odot \] | \( T_\text{eff} \) | \[ K \] | Mass | \[ M_\odot \] | Schaller et al. 1992 | Median | Std. Dev. |
|------|--------|------------|---------------|-------|------|-------------|---------------------|--------|-----------|
|      |        | Bertelli et al. 1994 | Claret 2004 |        |      |             |                     |        |           |
| 1    | 30122  | 3600       | 7.15−7.60    | 6.31−7.94 | 7.00 | 7.15 | 0.51 |
| 2    | 86414  | 2300       | 6.35−6.75    | 6.31    | 7.00 | 6.55 | 0.35 |
| 3    | 39138  | 1400       | 6.05−6.30    | 6.31    | 5.00−7.00 | 6.30 | 0.75 |
| 4    | 97278  | 2500       | 5.12−5.66    | 6.26    | 4.94−4.98 | 5.66 | 0.66 |
| 5    | 69996  | 2100       | 6.75−7.00    | 6.31    | 7.00 | 6.80 | 0.36 |
| 6    | 99473  | 848.6      | 4.18−4.63    | 3.98−5.01 | 4.00 | 4.00 | 0.35 |
| 7    | 76600  | 2704.9     | 7.25−7.65    | 7.94    | 7.00 | 7.25 | 0.49 |
| 8    | 67464  | 4428.8     | 8.50−8.80    | 7.94    | 9.00 | 8.50 | 0.53 |
| 9    | 79404  | 2504.2     | 7.30−7.90    | 7.94    | 7.00 | 7.60 | 0.48 |
| 10   | 32759  | 18900      | 10.95−12.90  | 9.97−12.52 | 8.97−11.94 | 11.94 | 0.49 |

From the resolved \( BVJHK \) magnitudes we calculate the \( A_V \) values using the selected colours mentioned before.

4 Luminosities

Since one does not measure the distance itself, but the parallax, we use the error dependent expectation values of the parallax, which lead to smaller distances. This treatment is introduced in Smith & Eichhorn (1996). We apply this correction to all stars in our sample using equation 21 in Smith & Eichhorn (1996). The errors of Hipparcos parallaxes are often as large as its value for a distance of \( \geq 1 \) kpc. Unfortunately OB-type stars are typically far from us. 1536 of the 2323 stars are within 600 pc that is a reliable distance for Hipparcos. Due to the small relative errors for this distances the Smith & Eichhorn (1996) correction does not strongly affect the distance estimate, while for stars with parallaxes \( \approx 1 \) mas this effect becomes important, see Figs. 3 and 4.

The luminosity of a star in units of \( L_\odot \) can be calculated by this familiar equation:

\[
L_{\text{bol}} = 10^{0.4(5 \log_{10} d - 5 + 4.74 - BC_V - m_V + A_V)},
\]

with the corrected distance \( d \) in parsec.

From spectral types we derived the temperatures \( T_\text{eff} \) using the Tables in Bessell et al. (1998), Kenyon & Hartmann (1995) and Schmidt-Kaler (1982). With temperature and luminosity we show all 2323 stars, singles and massive binaries, in the H-R diagram in Fig. 5. Our sample contains dozens or even more than hundred stars for most spectral types. This enables us to provide reliable statistic median
From Table 3 we obtain typical error weighted median masses and luminosities for different spectral types and sub-types. We list these masses (together with the luminosities using corrected parallaxes from Fig. 6) where at least five stars for one spectral sub-type are in the sample. Because of uncertain photometry we excluded binaries and all stars listed in Simbad with a range for their possible luminosity class. Note that the number of O stars in the sample is small and that they often have large distances (with large errors), i.e. their masses and luminosities are less reliable than for other spectral types.

| Sp. Type | Mass [M_☉] | Lbol [L_☉] | # |
|----------|------------|------------|---|
|          | Median     | Std. Dev.  | Median | Std. Dev. |
| LC I     |            |            |        |            |
| O9       | 24.25      | 5.80       | 146000 | 13000      | 9  |

| B0       | 13.75      | 3.37       | 18300  | 2300       | 16 |
| B1       | 11.98      | 1.70       | 12200  | 600        | 42 |
| B2       | 7.94       | 1.01       | 4900   | 40         | 61 |
| B3       | 6.31       | 0.72       | 2200   | 40         | 68 |
| B4       | 5.01       | 1.15       | 1300   | 50         | 20 |
| B5       | 5.00       | 0.51       | 800    | 20         | 83 |
| B6       | 4.65       | 0.72       | 580    | 30         | 36 |
| B7       | 4.00       | 0.59       | 490    | 10         | 46 |
| B8       | 4.00       | 1.23       | 530    | 60         | 11 |
|          |            |            |        |            |
| LC V     |            |            |        |            |
| O7       | 17.52      | 9.33       | 13900  | 700        | 6  |
| O9       | 19.60      | 4.33       | 36400  | 3100       | 13 |
| B0       | 15.00      | 2.83       | 16100  | 130        | 27 |
| B1       | 11.98      | 1.24       | 12520  | 150        | 81 |
| B2       | 8.50       | 0.62       | 4130   | 60         | 179|
| B3       | 6.55       | 0.42       | 1770   | 20         | 219|
| B4       | 5.75       | 0.64       | 1260   | 20         | 71 |

While for most spectral types the values from Schmidt-Kaler (1982) (who do not list errors) are consistent with ours, there is a tendency to smaller luminosities for LC I and III in our new data. This discrepancy is still present if we restrict our statistics to stars within 600 pc (corrected distances) or use uncorrected parallaxes for the luminosities (because most of the stars are within 600 pc where the Smith & Eichhorn (1996) correction is not important, see Figs. 6 and 7).

Wegner (2007) calculated luminosities from a star sample which is quite similar to ours, but shows only spectral types later than A0, with Hipparcos parallax (but extinctions only from $B-V$, not from $BVJHK$) and compared the result to the luminosities from Schmidt-Kaler (1982). Wegner (2007) found for late type supergiants the same differences as we: they are underluminous compared to Schmidt-Kaler (1982) by 1.5 magnitudes in average, in particular also the large discrepancy around spectral type K and M (up to two magnitudes).
Recently, photometric distances of 29 OB associations and many OB field stars were adjusted using Hipparcos parallaxes from Dambis et al. (2001). They found, that previous photometric distances overestimated the Hipparcos distances about 11% on average for these OB associations and about 20% for field stars, respectively.

With corrected luminosity and effective temperature we can estimate the stellar radius with the Stefan-Boltzman law. We show the stellar radii from those stars of our sample which are listed in Pasinetti-Fracassini et al. (2001) and our own radii in Fig. 8. Pasinetti-Fracassini et al. (2001) provide a list of radii measured directly with different methods between 1950 and 1997 (681 values for 246 stars). We see a good consistency of our radii to those of Pasinetti-Fracassini et al. (2001).

5 Masses

With luminosities and effective temperatures, we can estimate the masses of our stars by comparing their location in the H-R diagram with model mass tracks. We use evolutionary models from Schaller et al. (1992), Bertelli et al. (1994), and Claret (2004). The different authors provide evolutionary tracks for different metallicities, we present the masses for solar metallicity. The metallicity is only well known for few stars and affect the mass estimation only by a few percent. The differences in mass between the models with the same metallicities are comparable to this.

Owing to the discrepancies in the luminosities for supergiants, we fix the temperature first, that is much better known than the luminosity, within 10% tolerance taking possible uncertainties from the spectral type determination into account. We then determined the mass tracks with the best relative agreement to the given luminosities within their errors. Even if the luminosity is strongly underestimated and the relative deviation to the nearest mass track will be large, at least it will be on the main sequence. This avoids a systematic underestimation of the masses caused from underestimated luminosities.

The models of Schaller et al. (1992) underestimate the masses by 0.37% in median compared to the masses obtained from Bertelli et al. (1994), while Clarets (2004) model overestimates the masses about 2.7% in median compared to the masses from the model of Bertelli et al. (1994), i.e. they agree well. While Claret (2004) and Schaller et al. (1992) provide models for masses up to 120 M⊙, the models from Bertelli et al. (1994) give masses up to 34 M⊙ for solar metallicity. Therefore, if the mass estimation of a star using Schaller et al. (1992) or Claret (2004) results in 34 M⊙ or more, we did not use the results using Bertelli et al. (1994). We list the results of the first ten stars in Table 3.

Using the different results from the different models for each star, we find, that the mean of the standard derivation is 9.9% compared to the median of the masses themselves. We see this as good consistency. For 76% of the stars, the standard deviation of the mass is less than 10% of the median of the mass value and for 28% of the stars the standard deviation is less than 5%. The standard deviations of the mass values may underestimate the error of mass estimation.

Having determined the masses of all 2323 stars, we obtain median masses for the spectral sub-types depending on the LC. Likewise for the bolometric luminosities we have dozens, or even more than hundred, stars per spectral sub-type, i.e. the median masses should be robust against fluctuations and errors in the empirical data. We list these masses for stars with at least five entries in a spectral sub-type in Table 4. If a system appears in one of the used binary catalogues, we use its dynamical mass instead of our model-dependent masses. If one system appears in more than one of these catalogues, we use the median and the standard deviation (as error) from the different mass values.

From masses and luminosities in Table 4 we derive a mass-luminosity relation ($L \propto M^\beta$) with $\beta = 3.66 \pm 0.12$ for the main sequence stars (see Fig. 9).

We also compare the masses of the binaries with dynamical masses with our method of mass determination. We use the effective temperatures and luminosities (derived from $M_{bol}$) listed in Brancewicz & Dworak (1980), effective temperatures from listed spectral types and luminosities (derived from $M_{bol}$) in Bondarenko & Perevozkina (1996), Perevozkina (1999), and Surkova & Svechnikov (2004) to calculate own mass values (if a system appears in more than one catalogue we list the median of the different masses). Our masses are in good agreement but tend to smaller values (a factor of 1.5 in median, peak at ~10–20%) compared to the masses from the other authors (see Fig. 10).
Table 5  List of 36 binary systems where both components exceed $8 \, M_{\odot}$ from dynamical masses given in the binary catalogues discussed in the text (see also column seven). We list mass and spectral type ranges obtained from these catalogues for both components.

| Hip | Primary Sp. Type | Secondary Sp. Type | Mass $[M_{\odot}]$ Primary | Secondary | Ref. |

6 Supernova progenitors

We find 759 stars in our sample with median masses $\geq 8 \, M_{\odot}$ in total, 36 of them are the secondaries of a more massive primary (Table 5 and Fig. 11). Among them, in three systems the primary has a median mass $\geq 30 \, M_{\odot}$, i.e. may form a black hole. We list current masses in Table 5, but do not include binary interaction for predicting the final outcome.

Starting from the median mass values with the standard deviations ($1\sigma$) as errors we can give a maximum number of such systems (median + $1\sigma$), a median number (median masses) and a minimum number (median – $1\sigma$), see Table 6.

We also give the corresponding numbers for these progenitors within 600 pc in Table 6. This includes the Gould Belt that hosts 2/3 of the SN progenitors within this distance (Torra et al., 2000).

From the mass estimation we also obtain ages using the corresponding isochrones in the models. Given masses and ages we estimate the expected remaining life time of a star using the model in Maeder & Meynet (1989) and, hence, predict a SN rate for the near future (that should be similar to the SN rate of the recent past). This SN rate is stable until $\sim 10$ Myr in the future, then star formation and evo-
Our mean luminosities and masses are derived from dozens of stars for most spectral types, which should make our results reliable and robust against individual outliers. In our sample 1536 stars are within 600 pc and 2127 stars are within 1 kpc. For most spectral types and luminosity classes, our luminosities are smaller than those in Schmidt-Kaler (1982), in particular for supergiants, even if we restrict our luminosities to those stars with values of the parallax larger than its 3σ error or to stars closer than 600 pc.

7 Conclusions

Fig. 11 The complete star sample used in this work is represented by grey dots. Massive binaries are shown as black dots (with both components having masses \( \geq 8 \, M_\odot \)) from dynamical masses listed in Brancewicz & Dworak (1980), Bondarenko & Perevozkina (1996), Perevozkina (1999), and Surkova & Svechnikov (2004). We indicate a few OB associations, where we find clusters of massive stars, i.e. predict more supernovae in the near future (see Fig. 13). Both Magellanic Clouds (LMC and SMC) are indicated, which were left out for this work.

We stress that we restrict our sample to those massive stars within 3 kpc, which have both Hipparcos parallaxes and 2MASS JHK data, in order to estimate precise and accurate luminosities and masses. Hence, we miss several SN progenitor stars. Starting from 3694 stars (see Sect. 2) to 2323 stars in the final sample, we systematically underestimate the number of such systems at least by a factor of 1.2 within 600 pc and more than 1.6 for stars within 3 kpc. Therefore we only estimate the SN rate for the well investigated and more complete stars within 600 pc and multiply it with a factor of 1.2 (that still gives a lower limit of the rate), obtaining 17.4±4.2 events/Myr for the Gould Belt close to the past SN rate of the Gould Belt in Grenier (2000), also averaged over 10 Myr. The SN events are concentrated in OB clusters, in particular the Orion OB clusters and the Vela region (see Fig. 13).

Fig. 12 The supernova rate within 600 pc in the future (circles) obtained from the stars of our sample and multiplied with 2/3 (squares) for the Gould Belt rate (see text) compared with the rate of 20–27 events/Myr given in Grenier (2000) for the Gould Belt (dashed lines). Due to our selection criteria (see text) for the star sample, our rate is a lower limit. The average rate over 10 Myr is \( \geq 14.5\pm3.8 \) events/Myr for the Gould Belt and \( \geq 21.3\pm4.7 \) events/Myr within 600 pc. All errors are Poissonian.
Fig. 13 (online colour at: www.an-journal.org) Same as in Fig. 11, shown with the distribution of the supernova rate for the next 10 Myr (see also Fig. 12) including all massive stars within 600 pc. The colours indicate the normalised rate per Myr and square bin (longitude and latitude both divided in 25 bins). Note, that the supernova rate per area in Orion is 2–3 times higher than for the other clusters.

Table 6 Number of systems with at least one neutron star (NS) or black hole (BH) progenitor in the total sample (see text) and within 600 pc in parenthesis plus the corresponding number if both components of a binary system are NS and/or BH progenitors. The numbers are obtained from the median mass values (median numbers), the minimum (median mass value − 1σ) and the maximum (median mass value + 1σ) numbers of progenitors.

|          | Minimum | Median | Maximum |
|----------|---------|--------|---------|
| NS prog. within 3 kpc | 686 + 26 | 759 + 36 | 1004 + 43 |
| within 0.6 kpc | (287 + 12) | (356 + 19) | (485 + 25) |
| BH prog. within 3 kpc | 12 + 1 | 24 + 1 | 54 + 3 |
| within 0.6 kpc | (2 + 0) | (2 + 0) | (8 + 0) |

This has several reasons:

1. Hipparcos distances are smaller than previously used ground based distances. This effect of 20–30% in distance results in a revision of luminosity of 44–70%. We thereby confirm previous similar conclusions by Dambis et al. (2001) and Wegner (2007).

2. Many stars, especially supergiants, which were supposed to be single stars decades ago, are now known as multiple or double systems with their components on the main sequence. Schmidt-Kaler (1982) uses data from Code et al. (1976). 75% of the stars in Code et al. (1976) are known to be binaries or multiples today, but listed as single stars in Code et al. (1976).2

The masses we derived from our new luminosities using evolutionary models agree well with dynamical masses. We find 36 binaries with both components ≥8 M⊙ and estimated the SN rate for the next 10 Myr for the solar neighbourhood to be about one SN per 50 kyr. We have restricted our sample here to those massive stars within 3 kpc, which have both Hipparcos parallax and 2MASS JHK data. We will enlarge our sample including all possible supernova progenitors within 3 kpc in further work.

Information about the likely distribution of neutron stars in the solar neighborhood can be important for the design of searches for gravitational waves (GWs) with current interferometric detectors like GEO600, LIGO and VIRGO. Blind searches for previously unknown neutron stars radiating gravitational waves are computationally very expensive, so restriction of searches to specific regions of the sky, fre-

---

2 One of those stars is HD 68273, which was known as WC8 + O9I (in Code at al. 1976) and is now known as O9 + B3 + A0 + A0 (CCDM catalogue, Catalogue of the Components of the Double and Multiple stars, Dommanget & Nys 2000). The magnitudes $M_V$ (WC8) and $M_V$ (O9I) were measured as $(−4.8 ± 0.3)$ mag and $(−6.2 ± 0.2)$ mag, respectively, from Conti & Smith (1972). The distance was assumed to be 460 pc in Abt et al. (1976) but was revised to 258 pc in van der Hucht et al. (1997) using the Hipparcos parallax. The new distance yields to $M_V$ (WC8) = −3.7 mag and $M_V$ (O9I) = −5 mag.
quencies, and spin-down time-scales can improve the sensi-
tivity of searches. Of particular interest in current searches
are old, isolated neutron stars which have cooled down so
that they are no longer visible as X-ray sources, and which
might not be radio pulsars or might have pulsar beams that
are not directed toward us. Taking high kick velocities into
account, 140 neutron stars, younger than 4 Myr, should be
still present within 1 kpc (Palomba, 2005).

Current GW searches for isolated neutron stars contain
a spin-down parameter, which means that they can also
detect accelerating systems, such as sources in wide binary
systems. GW searches could easily be generalized to find
neutron stars in wide binaries, even potentially those with
accretion that leads to increased ellipticity and spin-up
rather than spin-down.
