Abstract

The evolution of spheroids of matter emitting gravitational waves and a null radiation field is studied in the realm of radiative Robinson–Trautman spacetimes. The null radiation field is expected in realistic gravitational collapse and can be either an incoherent superposition of waves of electromagnetic, neutrino or massless scalar fields. We have constructed the initial data identified as representing the exterior spacetime of uniform and non-uniform spheroids of matter. By imposing that the radiation field is a decreasing function of the retarded time, the Schwarzschild solution is the asymptotic configuration after an intermediate Vaidya phase. The main consequence of the joint emission of gravitational waves and the null radiation field is the enhancement of the amplitude of the emitted gravitational waves. Another important issue we have touched on is the mass extraction of the bounded configuration through the emission of both types of radiation.

1. Introduction

An outstanding problem of classical general relativity is the gravitational wave emission from the collapse of bounded distributions of matter to form black holes [1]. The knowledge of the underlying physical processes in which the nonlinearities of the field equations play a determinant role will be very useful in connection to the current efforts toward the detection of gravitational waves. Realistic models of collapse must include rotation as well as the emission of radiation [2] due to processes involving the matter fields inside the bounded source, therefore constituting a formidable problem to be tackled numerically [3]. In particular, it will be of enormous importance to know the amount of mass radiated away by gravitational waves, the generated wave fronts and the influence of other radiative fields, such as electromagnetic and neutrino fields, on the emission of gravitational waves.
Recently, we have studied the full dynamics of Robinson–Trautman (RT) spacetimes [4] that can be interpreted as describing the exterior spacetime of a collapsing bounded source emitting gravitational waves [5]. The process stops when the stationary final configuration, the Schwarzschild black hole, is formed, and this happens for all smooth initial data. An interesting possibility in extending this model is to include a null radiation field that can represent an incoherent superposition of electromagnetic waves, neutrino or massless scalar fields. Therefore, our objective here is to evolve the class of Robinson–Trautman geometries filled with pure radiation field [6] that correspond to the exterior spacetimes of spheroids of matter which are astrophysically reasonable distributions of matter.

In spite of being a restricted class of axisymmetric spacetimes, the RT geometries possess important attributes such as the asymptotic flatness and the presence of gravitational waves. As a consequence, these aspects warrant the use of RT spacetimes to model not only the emission of gravitational radiation by a bounded source but also the inclusion of the emission of other fields, which is more likely to occur, for instance in core collapse of massive stars [7]. In this context, another interesting issue that can be covered is the black hole recoil due to gravitational wave emission [8–10] which has been receiving a great deal of attention recently. On the other hand, the simplicity of the RT equations constitutes a valuable theoretical laboratory to test numerical strategies based on the Galerkin method as we have used presently that are distinct from the standard finite-difference techniques.

The paper is organized as follows. In section 2, we present the equations governing the evolution of radiative Robinson–Trautman spacetimes, along with the invariant characterization of gravitational waves through the Peeling theorem. In section 3, we derive the initial data for Robinson–Trautman that represent the exterior spacetime of uniform and non-uniform spheroids of matter. The procedure of integrating the set of nonlinear equations through the Galerkin method is outlined in section 4. Although not presenting the details here, we have improved the implementation of the Galerkin method by which the issues of accuracy and convergence were discussed in [11]. Section 5 is devoted to the presentation and discussion of the dynamics of the model and the gravitational wave patterns. The issue of mass loss due to the emission of gravitational waves is discussed in section 6, where we suggest the validity of a non-extensive relation between the fraction of the mass extracted and the mass of the formed black hole. Finally, in section 6 we present a summary of the main results as well as future perspectives. The linear approximation of the field equations is included in the appendix. Throughout the paper we use units such that $8\pi G = c = 1$.

2. Basic aspects of the radiative Robinson–Trautman spacetimes

The Robinson–Trautman metric can be expressed as [4]

$$ds^2 = \left( \lambda(u, \theta) - \frac{2m_0}{r} + 2r \frac{K}{\tilde{K}} \right) du^2 + 2du \, dr - r^2 K^2(u, \theta) (d\theta^2 + \sin^2 \theta \, d\phi^2),$$  \hspace{1cm} (1)

where $u$ is a null coordinate such that $u = \text{constant}$ denotes null hypersurfaces generated by the rays of the gravitational field and that foliates the spacetime globally; $r$ is an affine parameter defined along the null geodesics determined by the vector $\partial/\partial r$ and $m_0$ is a constant. The angular coordinates $(\theta, \phi)$ span the spacelike surfaces $u = \text{constant}$, $r = \text{constant}$ commonly known as the 2-surfaces. In the above expression, dot means derivative with respect to $u$ and $\lambda(u, \theta)$ is the Gaussian curvature of the 2-surfaces. Note that we are assuming axially symmetric spacetimes admitting the Killing vector $\partial/\partial \phi$.

The Einstein equations for the Robinson–Trautman spacetimes filled with a pure radiation field are reduced to
\[ \lambda(u, \theta) = \frac{1}{K^2} - \frac{K_{\theta\theta}}{K^3} + \frac{K_{\theta}^2}{K^4} \cot \theta \] (2)

\[ -6m_0 \frac{\dot{K}}{K} + \frac{\dot{\lambda} \sin \theta}{2K^2 \sin \theta} = E^2(u, \theta), \] (3)

where the subscript \( \theta \) denotes derivative with respect to the angle \( \theta \). The function \( E^2(u, \theta) \) appears in the energy–momentum tensor of the pure radiation field as

\[ T_{\mu\nu} = \frac{E^2(u, \theta)}{r^2} l_\mu l_\nu, \] (4)

where \( l_\mu = \delta^0_\mu \) is a null vector aligned along the degenerate principal null direction. The vacuum RT spacetime is recovered if \( E(u, \theta) = 0 \) and the case in which the energy density does not depend on \( \theta \) corresponds to the pure homogeneous radiation field.

The structure of the field equations is typical of the characteristic evolution scheme: equation (2) is a constraint or a hypersurface equation that defines \( \lambda(u, \theta) \), and equation (3) or the RT equation governs the dynamics of the gravitational field. In other words, from the initial data \( K(u_0, \theta) \) the constraint equation determines \( \lambda(u_0, \theta) \), and after fixing the function \( E^2(u, \theta) \), the RT allows one to evolve the initial data. Therefore, this equation will be the basis of our analysis of the gravitational wave emission together with a radiation field.

Several important works have been devoted to the evolution of the vacuum RT spacetimes focusing on the issue of the existence of solutions for the full nonlinear equation. The most general analysis on the existence and asymptotic behavior of the vacuum RT equation was given by Chrusciel and Singleton [12]. They have proved that for sufficiently smooth initial data the spacetime exists globally for positive retarded times and converges asymptotically to the Schwarzschild metric. Bicák and Perjés [13] extended the Chrusciel–Singleton analysis considering the pure homogeneous radiation field and established that for sufficiently smooth initial data the RT spacetime approaches asymptotically to the Vaidya solution [14]. In fact, the spherically symmetric Vaidya metric is a particular solution of the field equations (2) and (3).

Then, by assuming that \( K(u, \theta) = K(u) \), it follows from equation (2) that \( \lambda(u, \theta) = K^{-2}(u) \), and the RT equation yields

\[ K(u, \theta) = K(u) \propto \exp \left( -\frac{1}{6m_0} \int E^2(u) \, du \right). \]

The usual form of the Vaidya metric is recovered after a suitable change of coordinates, \( u \rightarrow \bar{u} = \int du/K(u) \), for which the following expression for the mass function emerges

\[ M_{\text{Vaidya}}(\bar{u}) = m_0 K^3(\bar{u}). \] (5)

By assuming further that the bounded collapsing matter emits radiation for some time until the Schwarzschild final configuration is settled down, its mass will be given by \( M_{\text{Schw}} = m_0 K^3_f \), where \( K_f \) is the final value of \( K(u, \theta) \).

It will be important to exhibit a suitable expression for the total mass–energy content of the RT spacetimes which we identify as the Bondi mass. To accomplish such a task it is necessary to perform a coordinate transformation to a coordinate system in which the metric coefficients satisfy the Bondi–Sachs boundary conditions (note that in the RT coordinate system the presence of the term \( 2r \dot{K}/K \) does not fulfil the appropriate boundary conditions). We basically generalize the procedure outlined by Foster and Newman [15] to treat the linearized problem, whose details can be found in [16, 17]. The result of interest is that Bondi’s mass function can be written for any \( u \) as \( M(u, \theta) = m_0 K^3(u, \theta) + \text{corrections} \), where the correction terms are proportional to the first and second Bondi-time derivatives of the news function; furthermore at the initial null surface \( u = u_0 \), these correction terms can
be set to zero by properly eliminating an arbitrary function of $\theta$ appearing in the coordinate transformations from RT coordinates to Bondi’s coordinates. Thus, the total Bondi mass of the system at $u = u_0$ is given by

$$M(u_0) = \frac{1}{2} m_0 \int_0^\pi K^3(u_0, \theta) \sin \theta \, d\theta.$$  

(6)

As a matter of fact, this expression will be very important to our analysis of the mass extraction by gravitational waves.

The invariant characterization of gravitational waves in RT spacetimes relies on the Peeling theorem, which is based on the algebraic structure of the vacuum curvature tensor of the geometry (1). The Peeling theorem [18] states that the vacuum Riemann or the Weyl tensor of a gravitationally radiative spacetime generated by a bounded source expanded in powers of $1/r$ has the general form

$$R_{ABCD} = \frac{N_{ABCD}}{r} + \frac{III_{ABCD}}{r^2} + \frac{D_{ABCD}}{r^3} + \cdots$$  

(7)

where $r$ is the parameter distance along the null vector field $\partial/\partial r$, and the curvature tensor is evaluated in an appropriate tetrad basis [5]. The quantities $D_{ABCD}, III_{ABCD}$ and $N_{ABCD}$ are of algebraic type D, type III and type N in the Petrov classification [20] and have the vector field $\partial/\partial r$ as a principal null direction. The above equation contains the information about the radiation zone, that is, for large values of the distance parameter $r$ the vacuum Riemann tensor is dominated by $N_{ABCD}/r$, which is Petrov type N. In other words, the field looks like a gravitational wave at large distances, in which the wave fronts are the $u = \text{constant}$ surfaces with $\partial/\partial r$ its propagation vector. In this vein, the non-vanishing of the scalars $N_{ABCD}$ is taken as an invariant criterion for the presence of gravitational waves in the wave zone.

For the RT spacetimes filled with a pure radiation field, the non-vanishing components of the Weyl tensor are

$$W_{2323} = -W_{0101} = 2W_{0212} = -\frac{2m_0}{r^3},$$

$$W_{0323} = \frac{\lambda_\theta}{2K^2},$$

$$W_{0303} = -\frac{D(u, \theta)}{r} + \frac{A(u, \theta) + E^2(u, \theta)}{r^2},$$

$$W_{0202} = -\frac{D(u, \theta)}{r} + \frac{A(u, \theta) - E^2(u, \theta)}{r^2},$$

(8)

where the functions $A(u, \theta)$ and $D(u, \theta)$ are given by

$$A(u, \theta) = \frac{1}{4K^2} \left( \lambda_{\theta\theta} - 2\frac{\lambda_\theta K_\theta}{K} - \lambda_\theta \cot \theta \right),$$

$$D(u, \theta) = \frac{1}{2K^2} \frac{\partial}{\partial u} \left[ \frac{K_{\theta\theta}}{K} - \frac{K_\theta}{K} \cot \theta - 2 \left( \frac{K_\theta}{K} \right)^2 \right].$$

(9)

Therefore the function $D(u, \theta)$ characterizes the wave zone and allows us to determine the evolution of the angular pattern of the emitted waves. It is important to remark that Gönnå and Kramer [17] have demonstrated, after performing a suitable coordinate transformation to the Bondi variables, that the news function of the RT metric is directly related to $D(u, \theta)$. Note that both expressions are the same as found in the vacuum case, but the influence of the radiation field on the gravitational wave amplitude is indirect since the evolution of $K(u, \theta)$ is altered by the inclusion of $E(u, \theta)$. 

4
3. Initial data: spheroids in RT spacetimes

A very important task is the construction of physically plausible initial data $K(u_0, \theta)$ for the RT equation. We have chosen the family of prolate or oblate spheroids due to their astrophysical relevance, and have also been motivated by the works of Lin et al [21] and Shapiro and Teukolsky [22] who have analyzed the collapse of gas spheroids in Newtonian and relativistic situations, respectively. Eardley [23] has focused on the collapse of marginally bound spheroids and the efficiency of the gravitational wave emission in this process. In order to construct the initial data corresponding to spheroids, we follow the procedure outlined in [10]. We start with the oblate spheroid initial data whose initial step is to consider the oblate spheroidal coordinates $(\zeta, \theta, \phi)$ defined by

$$
x = a\sqrt{\zeta^2 + 1}\sin \theta \cos \phi,
$$

$$
y = a\sqrt{\zeta^2 + 1}\sin \theta \sin \phi,
$$

$$
z = a\zeta \cos \theta,$$

where $a$ is a constant, $(x, y, z)$ are the usual Cartesian coordinates and $\zeta \geq 0$, $0 \leq \theta \leq \pi$ and $0 \leq \phi \leq 2\pi$. Note that the surfaces $\zeta = $ constant represent oblate spheroids described by

$$
x^2 + y^2 = a^2(\zeta^2 + \cos^2 \theta)(1 + \zeta^2 + \sin^2 \theta d\phi^2) + (1 + \zeta^2)^2\sin^2 \theta d\phi^2.
$$

The flat line element of the spatial surface $\Sigma$ is

$$
ds^2 = ds^2 = dx^2 + dy^2 + dz^2
$$

which expressed in the above set of coordinates becomes

$$
ds^2 = a^2[(\zeta^2 + \cos^2 \theta)(\frac{d\zeta^2}{1 + \zeta^2} + d\theta^2) + (1 + \zeta^2)^2\sin^2 \theta d\phi^2].
$$

Then, as the next step $\Sigma$ is taken as the spacelike surface of initial data with geometry defined by the following line element:

$$
ds^2 = K^2(\zeta, \theta)\left[(\zeta^2 + \cos^2 \theta)\left(\frac{d\zeta^2}{1 + \zeta^2} + d\theta^2\right) + (1 + \zeta^2)^2\sin^2 \theta d\phi^2\right].
$$

We assume time-symmetric initial data such that the vacuum Hamiltonian constraint [24] becomes

$$
\nabla^2 \Psi = 0,
$$

where $K = \Psi^2(\zeta, \theta)$ and $\nabla^2$ is the flat space Laplace operator in oblate spheroidal coordinates. The simplest solution of this equation is $\Psi = $ constant that implies $K = $ constant describing the Schwarzschild configuration. The general solution of this equation can be expanded as a series of the product of Legendre polynomials of the first and second kind [25]. By imposing suitable boundary conditions we obtain the following non-flat solution of (13) that represents the exterior region of an oblate with uniform mass distribution:

$$
\Psi(\zeta, \theta) = a\left[1 + \frac{B_0}{2a}\left(a(\zeta) + \frac{1}{2}\beta(\zeta) P_2(\cos \theta)\right)\right],
$$

where $a(\zeta) = \arctan(1/\zeta)$, $\beta(\zeta) = (1 + 3\zeta^2)\arctan(1/\zeta) - 3\zeta$, $P_2(\cos \theta)$ is the second-order Legendre polynomial and $B_0$ is a constant. The physical meaning of $B_0$ becomes clear after rewriting the metric (12) with the above solution for large $\zeta$ (which implies in $r \approx a\zeta$) or

$$
ds^2 = \left(1 + \frac{B_0}{2r} + O(r^{-3})\right)^4 ds^2_{\text{flat}}.
$$

Therefore, $B_0$ is identified as the mass of the oblate spheroid as measured by an observer at infinity.

At this point we can extract the initial data for the RT dynamics. Note that the conformal function (14) evaluated at $\zeta = \zeta_0 = $ constant contains all the information on the initial
data corresponding to the exterior region of an oblate spheroid. Then, since the degrees of freedom of the vacuum gravitational field are contained in the conformal structure of 2-spheres embedded in a 3-spacelike surface, as established by D’Inverno and Stachel [26] who studied the initial formulation of characteristic surfaces, we are led to adopt the following initial data:

\[
K(\zeta_0, \theta) = a \left[ 1 + \frac{B_0}{2a} \left( \alpha_0 + \frac{1}{2} \beta_0 P_2(\cos \theta) \right) \right]^2,
\]

(16)

with \( \alpha_0 = \alpha(\zeta_0) \) and \( \beta_0 = \beta(\zeta_0) \).

A similar procedure can be used in order to derive the initial data representing the exterior spacetime of a uniform prolate spheroid. Now we start by introducing prolate spheroidal coordinates \((\xi, \theta, \phi)\) [27],

\[
x = a \sqrt{\xi^2 - 1} \sin \theta \cos \phi, y = a \sqrt{\xi^2 - 1} \sin \theta \sin \phi, z = a \xi \cos \theta,
\]

in which \( \xi \geq 1 \) and the surfaces \( \xi = \xi_0 = \text{constant} \) define prolate spheroidal spheroids with foci at the points \((0, 0, \pm a)\). After a straightforward calculation following the same steps for the case of the oblate spheroids we obtain [25]

\[
K(\xi_0, \theta) = a \left[ 1 + \frac{B_0}{2a} \left( \bar{\alpha}_0 - \frac{1}{2} \bar{\beta}_0 P_2(\cos \theta) \right) + \sum_{n=0}^{\infty} a_n P_n(\cos \theta) \right]^2,
\]

(17)

where \( \bar{\alpha}_0 = 1/2 \ln((\xi_0 + 1)/(\xi_0 - 1)) \) and \( \bar{\beta}_0 = 1/2(3\xi_0^2 - 1) \ln(\xi_0 + 1)/(\xi_0 - 1) - 3\xi_0. \)

It is possible to go further and establish more general initial data that can be interpreted as describing the exterior spacetime of a spheroid endowed with a non-uniform distribution of matter. It can be shown that if one considers a prolate spheroid, for instance, the initial data can be generically expressed as

\[
K(\xi_0, \theta) = a \left[ 1 + \frac{B_0}{2a} \left( \bar{\alpha}_0 - \frac{1}{2} \bar{\beta}_0 P_2(\cos \theta) \right) + \sum_{n=0}^{\infty} a_n P_n(\cos \theta) \right]^2,
\]

(18)

where the closed expression for the additional term depends upon the way the matter inside the spheroid is distributed. When studying the consequences of such an initial data we will choose a suitable exact function of \( \theta \) instead of the above generic expression.

So far the initial data we have derived describe the vacuum exterior spacetime of bounded matter distributions. The derivation of the initial data for non-vacuum exterior spacetimes is a considerable difficult task due to the fact that we have to solve nonlinear constraint equations [24] instead of the Laplace equation whose analytical solution could be obtained. In this situation we assume that the same initial data as derived previously are extended to describe the exterior spacetime filled with pure radiation field, such that this model can account the collapse of a spheroid mass distribution emitting non-gravitational radiation.

4. Nonlinear approach: implementing the Galerkin method

In order to integrate numerically the field equations (2) and (3) we have applied the Galerkin method [28]. For the sake of completeness we briefly outline here the procedure found in [5, 11] and improved in [11]. Accordingly, the first step to establish the following Galerkin decomposition,

\[
K_0^2(u, x) = A_0^2 e^{\theta(u, x)} = A_0^2 \exp \left( \sum_{k=0}^{N} b_k(u) P_k(x) \right),
\]

(19)

where a new variable \( x = \cos \theta \) was introduced; \( N \) is the order of the truncation, and \( b_k(u), k = 0, 1, \ldots, N \) are the modal coefficients. The Legendre polynomials \( P_k(x) \) were chosen as the set of basis functions of the projective space, whose internal product is

\[
\langle P^\prime_j(x), P_k(x) \rangle = \int_{-1}^{1} P_j(x) P_k(x) \, dx = \frac{2\delta_{kj}}{2k + 1}.
\]

The next step is to substitute equation (19) into equation (2) to obtain an approximate expression for \( \lambda(u, x) \),

\[
\lambda_a(u, x) = e^{-Q(u,x)} A_0^2 \left( 1 + \sum_{k=0}^{N} \frac{1}{2} k(k+1)b_k(u) P_k(x) \right). \tag{20}
\]

Equations (19) and (20) are now inserted into the RT equation (3) yielding the residual equation

\[
\text{Res}(u, x) = 6m_0 \sum_{k=0}^{N} b_k(u) P_k(x) - \frac{1}{A_0^2} e^{-Q(u,x)} [(1 - x^2)\lambda' a]' + 2E^2(u, x), \tag{21}
\]

where the prime denotes derivative with respect to \( x \). In general, the residual equation approaches to zero when \( N \to \infty \) meaning that the decomposition (19) tends to the exact \( K(u,x) \). The Galerkin method establishes that the projection of the residual equation onto each basis function \( P_n(x) \) vanishes or \( \langle \text{Res}(u, x), P_n(x) \rangle = 0 \). These relations can be cast in the following way:

\[
\dot{b}_n(u) = \frac{(2n+1)}{12m_0A_0^2} \langle e^{-Q(u,x)} [(1 - x^2)\lambda' a]', P_n(x) \rangle - \frac{(2n+1)}{6m_0} \langle E^2(u, x), P_n(x) \rangle, \tag{22}
\]

where \( n = 0, 1, 2, \ldots, N \). Therefore, the dynamics of RT spacetimes is reduced to a system of \((N+1)\) ordinary differential equations for the modal coefficients or simply a dynamical system. It is worth mentioning that the issues of accuracy and efficiency of the dynamical system approach are discussed in [11].

To integrate the dynamical system (22) we need to provide the initial conditions \( b_k(u_0), k = 0, 1, 2, \ldots, N \) that represent the initial data \( K(u_0, x) \) constructed in the last section (equations (16)–(18)). These initial values are obtained from the Galerkin decomposition of \( K(u_0, x) \) (cf equation (19)), which yields

\[
b_j(u_0) = \frac{2}{\langle \ln K(u_0, x), P_j \rangle} . \tag{23}
\]

As we have mentioned in the last section the simplest form for the initial data corresponds to the Schwarzschild solution \( K(u_0, x) \) = constant that is described exactly using the above decomposition in which the only non-vanishing modal coefficient is \( b_0 \). In order to illustrate the effect of increasing the truncation order \( N \) we have exhibited, in figure 1, the plots of the relative error, R.E., between the approximate and exact expressions for the prolate spheroid described by equation (17), that is,

\[
\text{R.E.} = \frac{K(u_0, x) - K_a(u_0, x)}{K(u_0, x)}. \tag{24}
\]

Note that even for a small truncation order \( N = 4 \) the error is acceptable. In the numerical experiments of the following section we have fixed \( N = 14 \).

5. Numerical results

As we have shown, to integrate the set of equation (22) it is necessary to specify the initial conditions determined by the initial data \( K(u_0, x) \) (cf equation 23), and the function \( E(u, x) \). We start with the uniform spheroid initial data emitting homogeneous radiation (non-gravitational). It is reasonable to impose that \( E(u) \) is an arbitrary decreasing function of the retarded time \( u \). Among several possible choices [29] for \( E(u) \) we may select \( E^2(u) = E_0^2u^\alpha \exp(-\beta u) \), where \( E_0, \alpha \) and \( \beta \) are the positive constants; in particular if \( \alpha \neq 0 \) we describe a pulsed radiation. For any function \( E(u) \) it is important to remark that
Figure 1. Plot of the relative error between the approximate and exact initial data corresponding to a prolate spheroid for $a = 1, \beta_0 = 1.01$ and $E_0 = 2$. The curves correspond to truncation orders $N = 4, 8, 14, 20$. Note that even for the modest truncation $N = 4$ the error is acceptable.

the influence of the radiation field is basically due to the term $\langle 2E^2(u), P_n(x) \rangle = 4E^2(u)\delta_{n0}$ (see equation (22)) that only appears explicitly in the equation for $b_0(u)$; the influence on other modal coefficients is indirect through the nonlinear couplings between $b_0(u)$ and the remaining ones.

Let us consider the initial conditions $b_k(0), k = 0, 1, \ldots, N$ that correspond to the prolate spheroid described by equation (17). By inspecting this expression only even Legendre polynomials are present, and therefore only the even modal coefficients are initially distinct from zero. According to our previous work on the dynamics of vacuum RT spacetimes [5], we have shown that the odd modal coefficients remain unaltered while the even modal coefficients tend to zero asymptotically. The exception is $b_0(u)$ that approaches a constant value, consequently characterizing the Schwarzschild solution as the end state, which is in agreement with the analytical works of Chrushiel and Singleton [12]. The Schwarzschild mass of the final configuration is given by

$$M_{\text{BH}} = m_0 A_0^3 e^{\frac{2}{\alpha}(u_f)},$$

where $b_0(u_f)$ is the asymptotic value of the zeroth modal coefficient, and $u_f$ is large but finite. The final mass $M_{\text{BH}}$ is always smaller than the initial mass $M(u_0)$ as should be expected since part of the initial mass is carried away by gravitational waves. We will return to this issue in section 6.

We have performed several numerical experiments using the set of equation (22) with truncation order $N = 14$, and homogeneous radiation field $E^2(u)$ with distinct values of $E_0$, $\alpha$ and $\beta$. Physically, we have introduced a non-gravitational way of extracting mass that was discussed for the first time by Stachel [30], but it can be also seen from the linearized formula of mass loss (A.5). In this way, we expect that the mass of the final configuration be smaller than the similar one formed in the absence of the homogeneous radiation field. As a matter

\footnote{We have used the same criterion of [5].}
of fact, the numerical results have confirmed this feature; the Schwarzschild solution is the asymptotic configuration, that is $b_{2k} \to 0$, $k \geq 1$, $b_0 \to b_0(u_f) = \text{constant and smaller than found in the vacuum case.}$ Another important consequence of the homogeneous radiation field is that the approach to the Schwarzschild solution occurs faster than in the vacuum case. In figure 2, we have illustrated these features with the plots of the modal coefficients $b_0(u)$ and $b_4(u)$.

The dynamics of all modes together is shown in figure 3 for the vacuum and non-vacuum cases. Both graphs consist of sequences of polar plots of $K_a(u, x) = A_0 \exp \left( \frac{1}{2} \sum_{k=0}^{N} b_k(u) P_k(x) \right)$ for times $u$ until the Schwarzschild configuration (represented by a circle) is settled down. As expected, the presence of radiation produces a smaller circle due to the additional mass extracted.

The emission of gravitational waves constitutes the central physical aspect of the radiative Robinson–Trautman spacetimes. As we have seen the invariant characterization of the presence of gravitational waves was established on the basis of the Peeling theorem, where
Figure 3. Dynamics of all modal coefficients through the two-dimensional plots of $K(u,x)$ starting from the prolate spheroid initial data $(a = 1, B_0 = 0.5, \xi_0 = 1.05)$ at $u_0 = 0$ and for several times until the Schwarzschild final configuration (represented by a circle) is formed. The first graph refers to the vacuum RT spacetimes, while the second includes the homogeneous radiation field $E^2(u) = 4.0 \exp(-0.5u)$. One of the effects of the homogeneous radiation field is to produce a Schwarzschild configuration with smaller mass (a smaller circle as indicated by the axes).

$D(u, \theta)$ given by equation (10) contains all information about the angular and time dependence of the gravitational wave amplitude in the wave zone. This function can be conveniently expressed in terms of $x = \cos \theta$ and $Q(u, x)$ by

$$D(u, x) = \frac{1}{4A_0^2} e^{-Q(u,x)(1-x^2)} \left( \frac{\partial}{\partial u} \left( Q'' - \frac{1}{2} Q^2 \right) \right). \quad (25)$$

The angular distribution $D(u, x)$ at each instant $u$ is determined from the Galerkin decomposition $Q(u, x) = \sum_{k=1}^{N} b_k(u) P_k(x)$ along with the dynamical system for the modal coefficients. Although not appearing explicitly in the above expression, the radiation field alters the behavior of the modal coefficients and consequently the function $D(u, x)$.

A very useful way of depicting the pattern of the gravitational waves at the radiation zone is through polar plots of $D(u, x)$. In figure 4, we present such polar plots evaluated at the initial stages of evolution (as indicated by the arrows) and corresponding to the prolate spheroid initial data (17) for the cases of vacuum and homogeneous radiation field $E^2(u) = E_0^2 \exp(-0.5u)$. The patterns of emitted waves have symmetry of reflection by the plane $\theta = \pi/2 (x = 0)$, which is a direct consequence of the absence of all odd modes $b_{2k+1}$. Indeed, the symmetry of the pattern is consistent with the final configuration being a Schwarzschild solution at rest with respect to a distant observer, since no net momentum is carried out by the gravitational waves. In figure 5, similar plots are depicted taking into account the oblate spheroids initial data.

Two interesting aspects are worth remarking. The first is the predominant quadrupole structure of the pattern of gravitational waves, and the second is the influence of the homogeneous radiation field that does not alter the pattern of gravitational waves but enhance the amplitude of the peaks. To explain this result we might recall that the radiation field induces a faster decay of the modal coefficients (cf figure 2), and consequently produces higher values of $\dot{b}_0$. From equation (25), $D(u, x)$ depends directly on the derivatives of the modal coefficients, and therefore its value will be eventually increased. In order to show quantitatively the amplification of the gravitational wave amplitude due to the radiation field,
Figure 4. Polar plots showing the evolution of the angular pattern of gravitational waves emitted at the radiation zone for the vacuum (left panel) and non-vacuum cases (right panel), where the quadrupole mode is dominant. Note the directions indicated by $\theta = 0$ for the north pole and $\theta = \pi/2$ for the equatorial plane. The arrows indicate the first instants denoted by $u_0 = 0$, $u_1 = 0.06$, $u_2 = 0.18$ in which the angular pattern of $D(u, x)$ was evaluated. The homogeneous radiation field described by $E^2(u) = E_0^2 \exp(-0.5u)$ with $E_0^2 = 20$ does not affect the pattern of gravitational waves but increases the peaks as indicated above. In both cases, the initial conditions correspond to a prolate spheroid with $a = 1$, $\xi_0 = 1.01$, $B_0 = 0.1$.

Figure 5. Polar plots showing the evolution of the angular pattern of gravitational waves emitted by an oblate spheroid (16) for the vacuum (upper panel) and non-vacuum cases (lower panel). The structure now resembles that of the octupole pattern, and as in the case of the prolate spheroid the homogeneous radiation field increases the peaks of gravitational waves. Again the arrows indicate distinct instants $u_0 = 0$, $u_1 = 0.3$, $u_2 = 0.6$.

we have evaluated the total flux of gravitational radiation in the wave zone at each instant, which is proportional to

$$\sigma(u) = \int_{-1}^{1} |D(u, x)| \, dx,$$

(26)
Figure 6. Influence of the radiation field $E^2(u) = E_0^2 u \exp(-0.5u)$ on the behavior of the flux of the emitted gravitational waves. We have selected $E_0^2 = 3.0$, $4.0$ and $5.0$ in (a), (b) and (c), respectively. The initial data are the prolate spheroids (17) with $a = 1$, $\xi_0 = 1.01$, $B_0 = 1.0$.

according to a distant observer. In figure 6, $\sigma(u)$ is plotted for the vacuum and non-vacuum RT spacetimes indicated by (a), (b) and (c) for increasing values of $E_0$ taking into account that $E^2(u) = E_0^2 u \exp(-0.5u)$.

We now turn our attention to more general initial data that represent the exterior spacetime of a non-uniform prolate spheroid given by equation (18). Before discussing the numerical results, it is intuitive to expect that the collapse will proceed in a non-uniform way, meaning that distinct parts of the spheroid will collapse faster/slower than others. As a consequence, the pattern of gravitational waves should not display the same symmetry of reflection by the plane $\theta = \pi/2$ ($x = 0$) produced in the case of a uniform spheroid (cf figures 4 and 5). In this case, there will be a net flux of momentum carried out by gravitational waves that would be responsible for the recoil of the spheroid.

In order to study more quantitatively this feature, we consider, for the sake of convenience, that the last expression present on the rhs of equation (18) is written as $\sum_{n=0}^{\infty} a_n P_n(x) = A_0 \exp(-(x-x_0)^2)$, and that reflects somehow the description of the non-uniformity of the distribution of matter inside the spheroid or, alternatively, a perturbation of the uniform distribution. As a consequence, the Galerkin decomposition yields that all modal coefficients $b_k(0)$ are initially distinct from zero. We have first evolved the dynamical system (22) for the vacuum RT spacetimes ($E(u, x) = 0$), and contrary to what we have found previously all modal coefficients tend to constant values asymptotically (for large $u$) as illustrated in figure 7(a) with the plot of the modal coefficient $b_1(u)$. In figure 7(b), we have depicted some of the numerically resulting configurations $K_\mu(x) = \exp(1/2 \sum_{k=0}^{N} b_k(u) P_k(x))$. In order to identify these stationary configurations we recall that the other possible static solution of the RT equation is

$$K(x) = \frac{K_0}{\cosh \mu + x \sinh \mu},$$

(27)

where $K_0$ and $\mu$ are constants. This solution was found by Bondi et al [19] and represents a boosted black hole traveling with velocity $v = \tanh \mu$ along the symmetry axes. The total mass of this configuration is

$$M_0 = m_{\text{rest}} \cosh \mu = \frac{m_{\text{rest}}}{\sqrt{1 - v^2}},$$

(28)
Figure 7. (a) Behavior of $b_1(u)$ indicating that its asymptotic value is distinct from zero. The initial data are non-uniform oblate spheroids characterized by $\xi_0 = 1, B_0 = 1$ and $\sum_{n=0}^{\infty} a_n P_n(x) = A_0 \exp(-(x - 0.3)^2)$, where (i) $A_0 = 0.7$, (ii) $A_0 = 0.2$, (iii) $A_0 = 0.05$. (b) Plots of the final configuration $K_a(x) = \exp(1/2 \sum b_n(u) P_n(x))$. These curves are quite well fitted by the analytical expression (27) after choosing appropriate values for $K_0$ and $\mu$. In (c) we present the rms error between $K_a$ and $K(x)$ for each value of $A_0$.

where $m_{\text{rest}} = m_0 K_0^3$ is the rest mass ($\mu = 0$) with respect to a distant observer. Figure 7(c) shows the rms error between each numerical solution of figure 7(b) and the exact solution
Figure 8. The graph on the left shows the polar plot of $D(u, x)$ exhibiting a typical bremsstrahlung pattern of the gravitational radiation, whereas the detail of one of the lobes evaluated at $u = 0, u = 0.06$ and $u = 0.18$ is depicted on the right. Note that two effects are present: the amplitude of the gravitational waves decreases, and the inclination of the lobe changes forming a slightly less sharp forward cone in the direction of motion, as expected from the usual bremsstrahlung radiation.

(27) after convenient choices of $K_0$ and $\mu$. Therefore, if all modes are initially excited the asymptotic solution is a boosted black hole.

It is interesting to note that in the present situation the bounded source is accelerated from the rest at $u = 0$ until the emission of gravitational waves finishes. According to figure 8, the pattern of gravitational waves exhibits two prominent lobes whose symmetry line is the direction of recoil; also the inclination of the lobes increases with time (cf figure 8) together with the decrease of their amplitudes. These features are typical of the pattern of waves emitted by an accelerated point particle and are known to form a pattern of bremsstrahlung radiation [32].

The final task is to consider inhomogeneous radiation fields which seems to be more consistent in the realm of non-uniform spheroids. Although an inhomogeneous radiation field might arise as a consequence of general internal processes inside the spheroid where the non-uniform matter distribution may play a relevant role, we have not found any physically realistic function to describe such a form of radiation. Nonetheless, we can make some considerations about this situation. The dynamics of the modal coefficients will be directly affected by an inhomogeneous radiation field, as it can be seen from the projection $\langle E^2(u, x), P_n(x) \rangle$ that in general does not vanish for any $n$. Possibly, the decay of the modal coefficients to their final values will be done faster than in the absence of radiation, as in the case of homogeneous radiation. Besides the additional mechanism of extracting mass of the spheroid provided by the radiation field, there will also be an additional contribution to the total balance of linear momentum. Therefore, the final configuration will be in general a boosted black hole with the following characteristics: its mass is smaller and its velocity can be greater or smaller, respectively, than the mass and velocity of the corresponding boosted black hole found
without radiation. Concerning the pattern of gravitational waves, we expect that contrary to the homogeneous case the inhomogeneous radiation field will change the produced pattern of waves.

6. The mass loss

We have already studied the issue of mass loss due to the emission of gravitational waves before [5, 10, 16] in the realm of vacuum Robinson–Trautman spacetimes. The problem consisted in determining numerically the relation between the fraction of mass lost $\Delta$, or the efficiency of the process, with the final mass of the configuration $M_{BH}$. Here $\Delta$ is defined by [8]

$$\Delta \equiv \frac{|M(u_0) - M_{BH}|}{M(u_0)},$$

(29)

where $M(u_0)$ is the initial mass evaluated according to equation (6). As the main result we have shown that the set of numerically generated points ($M_{BH}, \Delta$) can be described by the following expression inspired from the Tsallis statistics [33],

$$\Delta = \Delta_{max}(1 - y^{-\gamma})^{\frac{1}{1-q}},$$

(30)

where $y = M_{BH}/m_0A_0^3$, $\Delta_{max}$ is the maximum efficiency, $\gamma$ and $q$ are the other parameters of the distribution law. We have found that for distinct initial data the best fit required that $q \approx 0$. However, the values of $\gamma$ and $\Delta_{max}$ depend on the particular choice of the initial data. Here the idea is to revise these results using our improved numerical method [11], to present some analytical work concerning the relation between $M_{BH}$ and $\Delta$, and to study the consequences of introducing a radiation field.

Before presenting the analytical and numerical results it is important to stress that equation (30) may not be considered an artificial relation connecting $\Delta$ and $M_{BH}$. To support this point of view we recall that a black hole can be understood as a thermodynamical system in equilibrium, therefore it is a state of maximum entropy. The question we address is the following: given initial data $K(u_0, x)$ now viewed as a ‘non-equilibrium thermodynamical state’, how much mass must be extracted through gravitational waves such that ‘thermodynamical equilibrium’ or the black hole formation is achieved? The empirical answer to this question is given by equation (30). Nevertheless, the choice of this function is inspired in two aspects: non-extensive relations involving thermodynamical quantities are typical of systems in which a long-range interaction such as gravitation is the relevant one [34], and the black hole entropy is a non-extensive quantity [35].

Let us consider the regime of small mass extraction or equivalently $\Delta \ll \Delta_{max}$. As a matter of fact this regime can be approximately described by the linearized equations (cf the appendix). Therefore, by setting $E^2(u, x) = 0$ into the equation that governs the loss of mass (equation (A.5)), $\Delta$ can be calculated analytically:

$$\Delta \simeq \frac{3}{2}(\epsilon_0(0) - \epsilon_0(u_f)) + \frac{3}{8} \sum_k \frac{\epsilon_k^2(0)}{2k + 1},$$

(31)

where $\epsilon(u_f)$ is the final value of $\epsilon_0(u)$. Note that $\Delta \sim O(\epsilon^2)$ implying that $\delta\epsilon_0 = \epsilon_0(u_f) - \epsilon_0(0) \sim O(\epsilon^2)$ (indeed, the linear approximation dictates that $\delta\epsilon_0 = 0$). On the other hand, $y = M_{BH}/m_0A_0^3 \approx 1 + 3/2\epsilon_0(u_f) \sim 1 + O(\epsilon)$. Combining these results it follows that

$$y - 1 \propto \Delta^{1/2} \Rightarrow y \approx 1 + \text{constant} \Delta^{1/2}.$$
By noting that the non-extensive relation (30) renders \( y \approx 1 + (\Delta / \Delta_{\text{max}})^{1-q}/\gamma \) in the limit \( \Delta \ll \Delta_{\text{max}} \), we conclude that \( q = 0.5 \), which is reproduced by the numerical result. Therefore, no matter what the initial data is, the regime of very small efficiency dictates that \( q = 0.5 \).

In figure 9(a), we have depicted the plots of the points \((M_{\text{BH}}, \Delta)\) generated numerically with the corresponding best fits of the function (30) (continuous lines). The oblate spheroid (16) was taken as the initial data where \( B_0 \) is the free parameter while \( a = 1 \) and \( \zeta = 0.01, 0.5 \) and 1.0. Note that \( \zeta \) is associated with the oblateness through \( f = 1 - \zeta / \sqrt{1 + \zeta^2} \), a measure of how much the initial distribution of matter deviates from the sphere. Therefore, according
Table 1. Theoretical and numerical values of the mass extracted at late stages due to the radiation field.

| $E_0^2$ | $\Delta_{\text{theoretical}}$ | $\Delta_{\text{numerical}}$ | Relative error |
|---------|--------------------------------|-----------------------------|----------------|
| 1       | 0.095 162 5820                | 0.095 162 582 30            | 0.315 $\times 10^{-6}$ |
| 0.5     | 0.048 770 5755                | 0.048 770 575 74            | 0.492 $\times 10^{-6}$ |
| 0.1     | 0.009 950 1663                | 0.009 950 166 51            | 0.213 $\times 10^{-7}$ |
| 0.05    | 0.004 987 5208                | 0.004 987 521 09            | 0.577 $\times 10^{-7}$ |
| 0.01    | 0.000 999 5002                | 0.000 999 500 43            | 0.230 $\times 10^{-8}$ |
| 0.005   | 0.000 499 8750                | 0.000 499 875 30            | 0.600 $\times 10^{-7}$ |
| 0.001   | 0.000 099 9950                | 0.000 099 995 60            | 0.599 $\times 10^{-7}$ |

To figure 9(a) the maximum efficiency attained increases with the oblateness (or decreases with $\zeta$) as should be expected. The numerical values obtained for the maximum efficiency are $\Delta_{\text{max}} \simeq 0.01038, 0.0510, 0.2417$, respectively, for $\zeta = 1.0, 0.5, 0.01$. It is worth noting that the last maximum efficiency is quite high due to the abnormally enlarged degree of oblateness. For the sake of comparison, in the realm of our solar system the highest oblateness belong to Saturn with $f_{\text{Saturn}} \simeq 0.097 (\zeta \simeq 2.08)$, and Jupiter $f_{\text{Jupiter}} \simeq 0.065 (\zeta \simeq 2.64)$, which are quite small.

We have noted that one of the most important consequences of the radiation field is to enhance the emission of gravitational waves, as a consequence, increasing the mass loss. The numerical relation between $M_{\text{BH}}$ and $\Delta$ is shown in figure 9(b), where we have considered for the homogeneous radiation field $E^2(u) = E^2_0 \exp(-0.5u)$. The effect of increasing $E_0$ is indicated by the successive deviations of the points corresponding to the vacuum case. Although we could not find a function to fit the data, it is possible to estimate analytically the fraction of mass extracted in the late stages dominated by the radiation field, which is described by the Vaidya solution. For the sake of simplicity, we consider that asymptotically $\epsilon_k \rightarrow 0, k \geq 1$ and $\epsilon_0 \rightarrow \text{constant}$. The late time behavior of $\epsilon_0(u)$ can be described approximately by the linear approach such that $\dot{\epsilon}_0 \approx -1/3m_0E^2(u)$, which yields $\delta\epsilon_0 \approx -E^2_0/3m_0\beta$. It can be shown that the fraction of mass loss is $\Delta \approx 1 - \exp(-E^2_0/2m_0\beta)$, which is in agreement with the numerical data as shown in table 1.

7. Final remarks

In this paper, we have studied the dynamics of the exterior spacetime of a bounded source emitting gravitational waves and a null radiation field characterized by the function $E(u, \theta)$ (cf equation (4)). The joint emission gravitational and some other type of radiation must be expected in a realistic non-spherical collapse. In order to provide a simple model with such features, we have derived the initial data that represent the exterior spacetimes of uniform and non-uniform spheroids of matter in the realm of Robinson–Trautman geometries.

Basically, the main implication of introducing the null radiation field is to produce a faster approach to the final configuration if compared with the case of vacuum ($E(u, \theta) = 0$), provided that $E(u, \theta)$ is regular and decays with the retarded time $u$. Indeed, as a consequence of this rapid relaxation toward the stationary configuration, the amplitude of the emitted gravitational waves is enhanced as illustrated in figures 4 and 5. In figure 6, a more quantitative view of this effect is exhibited. A similar feature can be found, for instance, in the process of the formation of supernova in which the asymmetric distribution of neutrinos can produce a growth in the gravitational wave emission [36].
The angular distribution of gravitational radiation at the wave zone bestows important information about the initial data and the final configuration. In this vein, distinct initial data will produce a distinct pattern of emitted waves, and this fact is clear from figures 4 and 5 whose initial data are uniform prolate and oblate spheroids; also the pattern of figure 8 is due to non-uniform prolate spheroid. On the other hand, if the pattern has symmetry of reflection by the plane $\theta = \pi/2$ the final configuration will be the Schwarzschild black hole, but if such symmetry is not present as shown in figure 8, a boosted black hole will be the end state. As we have seen, the emission of gravitational waves transports a net amount of linear momentum, which is responsible for the recoil of the isolated source due to energy–momentum conservation. In this process, the matter source is accelerated producing a typical pattern of bremsstrahlung [32] radiation of gravitational waves. The recoil of the remnant (a black hole or a pulsar) resulting from a non-spherical collapse is expected, and has been studied largely in the literature, mainly in the context of supernova explosions [9]. In particular, according to Eardley [8] pure gravitational wave recoil in the collapse applies only to the case of collapse to a black hole.

We have also revised the important issue of mass extraction due to the emission of gravitational waves in the realm of vacuum RT spacetimes. Our improved code has confirmed our previous numerical result concerning the non-extensive relation between the fraction of the mass extracted and the black hole mass. As a new result we have analytically derived that $q = 0.5$, which was confirmed by the numerical experiments.

Finally, the next step of our investigation will be to consider the dynamics of more general axisymmetric spacetimes described in the Bondi problem, where a numerical code based on the Galerkin method is under development. One of our interests is the mass loss due to gravitational wave extraction.

Appendix. Exact solution of the field equations: linear approximation

It is useful to study the linear regime of the field equations of RT spacetimes endowed with radiation field, which is a direct generalization of the Foster and Newman [15] solution for the vacuum case. Basically, we follow the approach of Foster and Newman by assuming that $K(u, \theta)$ is approximated as

$$K^2(u, \theta) \simeq A_0^2 \left[ 1 + \sum_{n=0} \epsilon_n(u) P_n(\cos \theta) \right], \quad (A.1)$$

where $A_0$ is a constant, $|\epsilon_n| \ll 1$ and $P_n(\cos \theta)$ is the Legendre polynomial of order $n$. For the vacuum case Foster and Newman have chosen $n \geq 2$ without loss of generality, since $n = 0$ and $n = 1$ both represent spheres (considering, of course, the submanifold $r^2 K^2 (d\theta^2 + \sin^2 \theta d\phi^2)$) that in the latter case has its center displaced at a distance $\epsilon_1 A_0$ along the axis of revolution. The linearized field equations are reduced to

$$\sum_{k=0} \epsilon_k P_n(\cos \theta) = - \sum_{n=0} k_n \epsilon_n P_n(\cos \theta) = \frac{E^2(u, \theta)}{3m_0}, \quad (A.2)$$
where \( k_n = \frac{\lambda^3_n}{12m_0} (n+2)!/(n-2)! \) is positive for all \( n \geq 2 \). Let us first consider the homogeneous radiation field, \( E^2(u, \theta) = E^2(u) \), for which the above equation can be rearranged as
\[
\epsilon_0(u) = -\frac{1}{3m_0} E^2(u), \quad \epsilon_n(u) = -k_n \epsilon_n(u). \tag{A.3}
\]

The second equation renders immediately \( \epsilon_n(u) = \epsilon_n(0) \exp(-k_n u) \), with \( \epsilon_n(0) \) being the initial value of \( \epsilon_n \) evaluated on the hypersurface \( u = u_0 = 0 \). From this analytical solution all coefficients \( \epsilon_n \to 0 \) as \( u \to \infty \), which is the same outcome of the vacuum RT geometries. The zeroth mode behaves as \( \epsilon_0(u) = \epsilon_0(0) - \frac{1}{3m_0} \int_{u_0}^{u} E^2(u) du \), indicating the approach to the Vaidya spacetime asymptotically. In this case, the corresponding line element that characterizes the Vaidya geometry can be obtained after the same coordinate transformation indicated in section 2.

By considering an inhomogeneous radiation field, we may set \( E^2(u, \theta) = \sum_{j=0}^{\infty} f_j(u) P_j(\cos \theta) \) to model a physically reasonable form for the energy density of the radiation. Substituting this expression in equation (A.2), the equations for each mode \( \epsilon_n(u) \) can be integrated yielding
\[
\epsilon_n(u) = \epsilon_n(0) e^{-k_n u} - \frac{1}{3m_0} e^{-k_n u} \int_{u_0}^{u} f_n(u) e^{k_n u} du. \tag{A.4}
\]

If \( n = 0 \) the solution corresponding to the homogeneous radiation case provided \( E^2(u) = f_0(u) \) is recovered. Again, we also may set \( f_1(u) = 0 \) without loss of generality. For those modes \( n \geq 2 \), the first term on the rhs vanishes in the limit \( u \to \infty \), and the long term behavior of \( \epsilon_n(u) \) is governed by the second term. It is possible to know the outcome of this asymptotic limit without specifying the functions \( f_n(u) \), \( n \geq 2 \). For instance, suppose that all \( f_n(u) \) are regular in some interval of time, say \( u_0 \leq u \leq u_1 \), representing a pulsed emission of radiation, or even be decreasing functions such that \( \lim_{u \to \infty} f_n(u) = 0 \). As a consequence, the second term on the rhs vanishes asymptotically rendering \( \epsilon \to 0 \) as \( u \to \infty \). Under these conditions and, in addition, assuming further that \( \lim_{u \to \infty} \int_{u_0}^{u} E^2(u) du \) is finite, the asymptotic state will be a Schwarzschild black hole.\(^2\)

As a final part of our study we generalize the original result of Foster and Newman on the change in the total mass energy of the system. We have followed an alternative approach (instead of using the Newman–Penrose formalism), which consists of expressing the RT equation in terms of the mass function \( M(u) \), \( 2m_0 \int_{u_0}^{u} K^2(u, \theta) \sin \theta d\theta \) and taking into account the linearized solution (equations (A.1) and (A.2)). After some steps and considering the homogeneous radiation field for the sake of simplicity, we have obtained
\[
\frac{\partial M(u)}{\partial u} = -\frac{1}{16A_0} \sum_n \frac{(n+2)!}{(n-2)!} \frac{\epsilon_n^2(u)}{2n+1} - \frac{A_0^3}{2} \frac{E^2(u)}{2} \left( 1 + \frac{3}{2} \epsilon_0(u) \right). \tag{A.5}
\]

The first term on the rhs, found by Foster and Newman, means that the mass loss by gravitational wave extraction is a second-order effect, while the second term accounts for the mass change due to the radiation field. In this sense, we can interpret the present linearized solution as representing a bounded source emitting gravitational waves and a null radiation field.

\(^2\) We may note that if \( \lim_{u \to \infty} f_n = \text{constant}, \ n \geq 2 \), and keeping the same restriction imposed on the function \( E^2(u) \), the corresponding modal coefficient approaches a finite asymptotic value, producing, as a consequence, a stationary and axisymmetric spacetime emitting a stationary and inhomogeneous radiation field. It seems, nevertheless, a not physically feasible situation.
