ABSTRACT
Objective To evaluate the protective efficacy of co-trimoxazole prophylaxis against malaria in HIV exposed children (uninfected children born to HIV infected mothers) in Africa.
Design Non-blinded randomised control trial Setting Tororo district, rural Uganda, an area of high malaria transmission intensity Participants 203 breastfeeding HIV exposed infants enrolled between 6 weeks and 9 months of age Intervention Co-trimoxazole prophylaxis from enrolment until cessation of breast feeding and confirmation of negative HIV status. All children who remained HIV uninfected (n=185) were then randomised to stop co-trimoxazole prophylaxis immediately or continue co-trimoxazole until 2 years old.
Main outcome measure Incidence of malaria, calculated as the number of antimalarial treatments per person year. Results The incidence of malaria and prevalence of genotypic mutations associated with antifolate resistance were high throughout the study. Among the 98 infants randomised to continue co-trimoxazole, 299 malaria cases occurred in 92.28 person years (incidence 3.24 cases/person year). Among the 87 infants randomised to stop co-trimoxazole, 400 malaria cases occurred in 71.81 person years (5.57 cases/person year). Co-trimoxazole prophylaxis yielded a 39% reduction in malaria incidence, after adjustment for age at randomisation (incidence rate ratio 0.61 (95% CI 0.46 to 0.81), P=0.001). There were no significant differences in the incidence of complicated malaria, diarrhoea, pneumonia, hospitalisations, or deaths between the two treatment arms. Conclusions Co-trimoxazole prophylaxis was moderately protective against malaria in HIV exposed infants when continued beyond the period of HIV exposure despite the high prevalence of *Plasmodium* genotypes associated with antifolate resistance.
Trial registration Clinical Trials NCT00527800

INTRODUCTION
HIV and malaria are two of the deadliest infectious diseases, together accounting for more than four million deaths annually worldwide and more than a million deaths in children aged less than 5 years in sub-Saharan Africa.12 Malaria prevention is especially important in children infected with HIV or exposed to HIV (uninfected children born to HIV infected mothers) given the increased susceptibility of these children to severe illness and death.2,5 The primary method of malaria prevention in young children is the use of bed nets treated with insecticide. However, there is now renewed interest in chemoprevention, the use of antimalarial drugs to prevent disease. One option for chemoprevention is the use of daily co-trimoxazole prophylaxis, based on evidence from observational cohorts of HIV infected children and a single randomised control trial of HIV uninfected children showing that co-trimoxazole prophylaxis protects children from malaria.6-9

The World Health Organization (WHO) recommends placing all infants of HIV infected mothers on co-trimoxazole prophylaxis starting at 6 weeks of age until cessation of breast feeding and exclusion of HIV infection.10 This guideline stems from evidence that co-trimoxazole prophylaxis protects HIV infected children from common opportunistic infections,11-13 including malaria.6,9 However, there are no studies on the protective efficacy of co-trimoxazole prophylaxis against malaria among HIV exposed, uninfected infants. More than two million infants are born to HIV infected African mothers each year, with more than 90% remaining uninfected throughout breast feeding.14-16 To exclude HIV infection in these children, HIV DNA testing by polymerase chain reaction (PCR) is required because of the persistence of maternal HIV antibodies in infant blood until 18 months of age. However, access to PCR testing remains extremely limited in most resource poor settings, and so large numbers of HIV exposed children throughout...
Africa continue taking co-trimoxazole prophylaxis until 18 months old, when exclusion of HIV infection by antibody testing becomes possible.

We conducted a randomised clinical trial to examine whether prolonged daily co-trimoxazole prophylaxis beyond the period of breast feeding provides sustained protective efficacy against malaria in HIV uninfected children born to HIV infected mothers in an area of high malaria transmission intensity in rural Uganda.

METHODS
Study setting and enrolment of participants
The study was conducted in Tororo, a rural setting located in southeastern Uganda, where malaria is holoendemic and the inoculation rate from insect bites is 391 infective bites per person year.17 We used convenience sampling to enrol a cohort of HIV exposed infants from the Mother and Child Health Clinic of Tororo District Hospital and the AIDS Support Organization (TASO) between August 2007 and April 2008. Mothers were not enrolled in the study, and their HIV infection was confirmed by serology through a national HIV testing programme.

Infants’ eligibility criteria included age 6 weeks to 9 months, documented HIV uninfected status of infant and HIV infected status of mother, current breast feeding, residence within 30 km radius of the study clinic, parent’s or guardian’s agreement to come to the study clinic for any febrile episode or other illness and to avoid medications administered outside the study protocol, absence of active medical problem requiring inpatient evaluation at the time of screening, and parent’s or guardian’s informed consent. All infant participants underwent a standardised clinical history and a physical examination at enrolment including thick and thin blood smears and a complete blood count. In addition, all participants were provided with a bed net treated with long lasting insecticide and their parents or guardians were instructed in its use. Daily co-trimoxazole prophylaxis was prescribed to all infant participants at enrolment, and to their HIV infected mothers if they were not already taking co-trimoxazole prophylaxis was determined from the monthly visits, where children’s breast feeding status and practices were assessed by asking the mothers how they had been feeding their child for the previous seven days. Routine phlebotomy for a complete blood count was performed every 90 days for each participant.

At each follow-up visit, study clinicians assessed participants for adverse events according to standardised criteria based on guidelines from the WHO and National Institutes of Health. Adverse events were defined as untoward medical occurrences, following the guidelines of the International Conference on Harmonization,18 and serious adverse events were defined as experiences resulting in death or life threatening events, inpatient hospitalisation, persistent or substantial incapacity, or medical or surgical intervention to prevent serious outcomes. Study participants were withdrawn from the study for permanent movement out of the study area, if they could not be located by study staff for >60 consecutive days, withdrawal of informed consent, inability to adhere to the study schedule and procedures, or inability to tolerate study drugs.

Treatment allocation and study drug administration
Six to eight weeks after cessation of breast feeding, each participant was tested for HIV infection by DNA PCR. Participants who acquired HIV during breast feeding were excluded from the study but continued to be followed up and cared for in the clinic as part of another study.

 Those who remained HIV uninfected after cessation of breastfeeding were randomised to discontinue co-trimoxazole prophylaxis immediately or to continue daily co-trimoxazole prophylaxis until 2 years of age. A randomisation list was computer generated by an off-site investigator. Sequentially numbered, sealed envelopes containing the prophylaxis assignments were prepared from the randomisation list. The study nurse assigned prophylaxis numbers sequentially and allocated co-trimoxazole prophylaxis or no prophylaxis by opening the envelope corresponding to the prophylaxis number. Participants randomised to continue co-trimoxazole prophylaxis were given a month’s supply of the drug at each routine visit (every 30 days).

A nurse administered co-trimoxazole syrup and tablets according to weight based guidelines. Young children weighing <15 kg were prescribed standardised medical evaluation. A set of algorithms was developed to guide treatment for common illnesses. Drugs with antimarial activity were avoided for the treatment of non-malarial illnesses when possible.

Monthly routine assessments were done in the study clinic to ensure adherence to the study protocol, drug use, and use of the insecticide treated bed net. Adherence to co-trimoxazole prophylaxis was determined monthly from responses to a validated questionnaire regarding the number of doses taken in the past three days and the percentage of doses taken in the past month. The date of breast feeding cessation was determined from the monthly visits, where children’s breast feeding status and practices were assessed by asking the mothers how they had been feeding their child for the previous seven days. Routine phlebotomy for a complete blood count was performed every 90 days for each participant.

At each follow-up visit, study clinicians assessed participants for adverse events according to standardised criteria based on guidelines from the WHO and National Institutes of Health. Adverse events were defined as untoward medical occurrences, following the guidelines of the International Conference on Harmonization,18 and serious adverse events were defined as experiences resulting in death or life threatening events, inpatient hospitalisation, persistent or substantial incapacity, or medical or surgical intervention to prevent serious outcomes. Study participants were withdrawn from the study for permanent movement out of the study area, if they could not be located by study staff for >60 consecutive days, withdrawal of informed consent, inability to adhere to the study schedule and procedures, or inability to tolerate study drugs.

Treatment allocation and study drug administration
Six to eight weeks after cessation of breast feeding, each participant was tested for HIV infection by DNA PCR. Participants who acquired HIV during breast feeding were excluded from the study but continued to be followed up and cared for in the clinic as part of another study.

 Those who remained HIV uninfected after cessation of breastfeeding were randomised to discontinue co-trimoxazole prophylaxis immediately or to continue daily co-trimoxazole prophylaxis until 2 years of age. The study nurse assigned prophylaxis numbers sequentially and allocated co-trimoxazole prophylaxis or no prophylaxis by opening the envelope corresponding to the prophylaxis number. Participants randomised to continue co-trimoxazole prophylaxis were given a month’s supply of the drug at each routine visit (every 30 days).

A nurse administered co-trimoxazole syrup and tablets according to weight based guidelines. Young children weighing <15 kg were prescribed

Follow up of study participants
Study participants were followed for all their medical problems in a dedicated study clinic open seven days a week from 8 am to 5 pm with after-hours care available at the Tororo District Hospital adjacent to the study clinic. Parents or guardians were encouraged to avoid using outside medications and to bring their infant to the study clinic or hospital any time the child was ill (transportation costs were reimbursed). Children who presented with new medical problems underwent
together of less than four days.

Gastroenteritis was defined as diarrhoea and vomiting bloody or purulent stool by examination or history.

Two weeks or longer. Dysentery was defined as grossly bloody stools on more than three watery stools a day by examination or history.

Chronic diarrhoea was defined as more than five watery stools a day for two weeks or longer. Dysentery was defined as grossly bloody or purulent stool by examination or history. Gastroenteritis was defined as diarrhoea and vomiting together of less than four days’ duration.

Respiratory tract infections were included in the analysis if the participant was diagnosed with pneumonia or severe pneumonia. Pneumonia was defined as fever and cough with adventitious lung sounds or respiratory distress, or both. Severe pneumonia was defined as pneumonia with severe respiratory distress requiring chest radiography, hospitalisation, and intravenous antibiotics. Upper respiratory tract infections were not included in the analysis.

Diagnosis of diarrhoea and respiratory tract infections

Diarrhoea was included in the analysis if the participant was diagnosed with acute diarrhoea, chronic diarrhoea, dysentery, or gastroenteritis. Acute diarrhoea was defined as more than five watery stools a day by examination or history.

Chronic diarrhoea was defined as more than five watery stools a day by examination or history. Gastroenteritis was defined as diarrhoea and vomiting together of less than four days’ duration.

Diagnosis and management of malaria

Medical diagnoses were made by medical officers using predetermined criteria. Participants who presented to the clinic with a documented fever (tympanic temperature ≥38.0°C) or history of fever in the previous 24 hours had blood collected by finger prick for a thick blood smear for malaria. If parasites were present, malaria was diagnosed regardless of parasite density. Complicated malaria was diagnosed in participants with a malaria diagnosis and either danger signs or criteria for severe malaria.20 Study participants >4 months old and weighing ≥5 kg with uncomplicated malaria diagnosed were randomly assigned to receive either open label artemether-lumefantrine or dipydroartemisinin-piperazine at the time of their first episode of malaria and received the same treatment for all subsequent episodes of uncomplicated malaria diagnosed during the study as part of a nested randomised drug efficacy trial.21 Children aged <4 months or weighing <5 kg with uncomplicated malaria and children with severe or complicated malaria were treated with standard doses of quinine.

Participants with malaria diagnosed were asked to return on days 1, 2, 3, 7, 14, 21, 28, and any other day they were ill. Follow-up evaluations consisted of a standardised medical history and physical examination. Blood was obtained by finger prick for thick blood smears and storage on filter paper on all follow-up days except day 1. Treatment outcomes were classified according to WHO guidelines.20 Outcomes designated as treatment failures included early treatment failures (complicated malaria or failure to adequately respond to treatment on days 0–3), late clinical failures (complicated malaria or fever and parasitaemia on days 4–28), and late parasitological failures (asymptomatic parasitaemia on days 7–28).

Diagnosis of diarrhoea and respiratory tract infections

Diarrhoea was included in the analysis if the participant was diagnosed with acute diarrhoea, chronic diarrhoea, dysentery, or gastroenteritis. Acute diarrhoea was defined as more than five watery stools a day for children aged <1 year and more than three watery stools a day for children aged ≥1 year of age lasting for less than two weeks. Chronic diarrhoea was defined by the same criteria as acute diarrhoea but lasting for two weeks or longer. Dysentery was defined as grossly bloody or purulent stool by examination or history. Gastroenteritis was defined as diarrhoea and vomiting together of less than four days’ duration.

Laboratory procedures

Before enrolment, all participants were tested for HIV infection by DNA PCR (Amplicor HIV-1 DNA PCR Test, version 1.5, Roche, Branchburg NJ, USA) using dried blood spots collected on filter paper. Mothers were previously tested at the antenatal clinic by HIV rapid antibody testing or enzyme linked immunosorbent assay (ELISA) antibody testing following national HIV testing algorithms.22 All participants were retested at six to eight weeks after complete cessation of breastfeeding with the PCR test, and at 18 months of age with both antibody testing (Determine Rapid test for HIV-1, Abbott Laboratories, Abbott Park IL, USA) and PCR assay of dried blood spots. All positive PCR results were confirmed by repeat bleeding and testing using quantitative HIV RNA PCR (Cobas Amplicor HIV-1 RNA Monitor Test, version 1.5, Roche).

Thick smears were stained with 2% Giemsa stain for 30 minutes, and parasite density was estimated using a rigorous quality control system previously described.8 Parasite species was determined on the day that malaria was diagnosed using nested PCR of 18S small subunit ribosomal DNA as previously described.23 Haemoglobin measurements were made using a portable spectrophotometer (HemoCue, Angelholm, Sweden) on days 0 and 28 of a given malaria episode or on the day of recurrent malaria.

We randomly selected 148 malaria episodes from each treatment arm divided equally into four periods of six months each (December 2007 to May 2008, June 2008 to November 2008, December 2008 to May 2009, and June 2009 to November 2009) to test for markers of antifolate resistance, as previously described.24–27 Using filter paper specimens collected on the day of malaria diagnosis, we tested for the presence of three mutations in the dihydrofolate reductase gene (dhfr 108N, 51I, and 59R) and two mutations in the dihydropteroate synthase gene (dhp 437G and 540Q) commonly found in East Africa. Additionally, we tested for one dhfr mutation (164L) and three dhp mutations (436S, 581G, and 613S) rarely found in Africa, but also associated with antifolate resistance.27 Specimens were classified as wild type or pure mutant, or mixed (both mutant and wild type alleles detected in the same specimen).

Data were double entered in Epi-Info, and statistical analysis was performed with Stata version 10 (Stata, College Station, TX, USA) and SPSS version 17 (SPSS, Chicago, IL, USA) using a two-tailed significance level of 5%.
College Station TX, USA). Efficacy and safety data were evaluated based on an intention to treat analysis including all participants who were randomised to continue or discontinue co-trimoxazole prophylaxis. Malaria incidence was defined as the number of new episodes of malaria per person time at risk. Time at risk included time from the day after randomisation until each child reached 2 years of age or was withdrawn from the study, whichever came first. In calculating the incidence of malaria, episodes of malaria and time at risk were censored for 14 days after start of each malaria treatment as children were not at risk of acquiring malaria during this period. Using molecular genotyping, we have shown that over 95% of malaria episodes occurring more than 14 days after initiation of antimalarial therapy were due to new infections.25

Cumulative risks of developing a first episode of malaria after randomisation were estimated with the Kaplan-Meier product limit formula. Data were censored for patients who were prematurely withdrawn from the study. Comparison of survival curves was made using the log rank test. Comparisons of the incidence of malaria, complicated malaria, diarrhoea, respiratory tract infections, hospitalisations, and mortality were made with negative binomial regression, with adjustment for age at randomisation. Protective efficacy was defined using an incidence rate ratio (incidence of malaria among children continuing co-trimoxazole vs incidence among those who stopped). We used generalised estimating equation methods with exchangeable correlation structure to account for repeated measures among the same individuals in comparing the association of co-trimoxazole prophylaxis with characteristics of malaria episodes and the presence of the dhfr and dhps mutations. A P value <0.05 was considered significant.

RESULTS

Trial profile and baseline characteristics

A total of 203 HIV exposed breastfeeding infants were enrolled between August 2007 and April 2008 (fig 1). Ten infants (5%) were withdrawn and eight (4%) seroconverted to HIV infected status before randomisation. With cessation of breastfeeding, infants of HIV infected mothers were no longer considered to be at risk of acquiring HIV infection. After confirmation of negative HIV status, 185 infants were randomised either to continue co-trimoxazole prophylaxis (n=98) or to stop prophylaxis (n=87), and a total of 170 completed follow-up (fig 1).

Table 1 shows the participants’ baseline characteristics. There were no significant differences between the two study arms in age at randomisation, time at risk and malaria incidence before randomisation, percentage time using the insecticide treated bed net, adherence to continuing or stopping co-trimoxazole after randomisation, or percentage of participants living in Tororo town (associated with a lower incidence of malaria compared with living outside of town).

Protective efficacy of co-trimoxazole prophylaxis against malaria

There were 699 episodes of malaria in total: 299 episodes among participants randomised to continue co-trimoxazole prophylaxis and 400 episodes among those randomised to discontinue co-trimoxazole. Nine episodes were caused by non-falciparum species: five among participants who continued co-trimoxazole prophylaxis (Plasmodium vivax n=1, and P malariae n=3) and four among those who stopped co-trimoxazole after breast feeding (P ovale n=2, P malariae n=1, and P vivax n=1). Among the 98 infants randomised to continue co-trimoxazole, 72 had at least one episode of malaria

Table 1 Baseline characteristics of 185 children at the time of randomisation to continued co-trimoxazole prophylaxis versus no prophylaxis. Values are numbers (percentages) unless stated otherwise

| Characteristic | Co-trimoxazole prophylaxis |  |
|---------------|----------------------------|---|
|               | Continued (n=98)            | Stopped (n=87) |
| Female        | 45 (46)                    | 47 (54) |
| Median (interquartile range) age (months): | | |
| At study enrolment | 3.2 (2.3–5.7) | 3.9 (2.0–6.8) |
| At stopping breast feeding | 7.2 (6.1–10.0) | 7.6 (6.8–10.8) |
| At randomisation | 9.6 (8.3–12.4) | 10.0 (8.9–13.5) |
| Incidence* (95% CI) of malaria before randomisation | 1.39 (1.08 to 1.76) | 1.32 (1.00 to 1.70) |
| Living in urban area of Tororo town | 19 (19) | 16 (18) |

*No of episodes/person year
during follow-up (cumulative risk 75.7%). Among the 87 children randomised to stop co-trimoxazole, 78 had at least one episode of malaria during follow-up (cumulative risk 93.4%). Figure 2 shows that there was a significant difference in the malaria-free survival curves between the two study arms ($P = 0.003$).

From the time of randomisation until each participant reached 2 years of age, the incidence of malaria was 3.24 episodes/person year (95% confidence interval 2.89 to 3.63) among participants who continued co-trimoxazole prophylaxis and 5.57 episodes/person year (5.04 to 6.14) among participants who stopped prophylaxis, representing a 39% lower risk of malaria for the children who continued taking co-trimoxazole ($\text{IRR} = 0.61$ (95% confidence interval 0.46 to 0.81, $P = 0.001$) (fig 3).

In investigating whether the protective effect of co-trimoxazole changed over time, we found there was no difference in the protective efficacy during the first 30 days after randomisation ($\text{IRR} = 0.83$ (0.45 to 1.53), $P = 0.55$) compared with the period from 30 days after randomisation to 2 years of age ($\text{IRR} = 0.59$ (0.44 to 0.80), $P < 0.001$) ($P = 0.30$ for interaction term). Apart from the period immediately after randomisation, the difference in the incidence of malaria between those children taking co-trimoxazole prophylaxis and those who stopped co-trimoxazole was constant with increasing time after randomisation and with increasing age (fig 4).

There were three episodes of complicated malaria among the participants randomised to continue co-trimoxazole prophylaxis and four episodes among those randomised to stop co-trimoxazole (incidence rate ratio 0.59, $P = 0.50$). Eight hospitalisations and two deaths occurred among the children randomised to continue co-trimoxazole, compared with four hospitalisations and one death among those randomised to stop co-trimoxazole ($P = 0.79$ and $P = 0.61$, respectively).

Protective efficacy of co-trimoxazole prophylaxis against diarrhea and respiratory tract infections

From the date of randomisation to 2 years of age, the children randomised to continue co-trimoxazole had 189 episodes of diarrhea and 33 episodes of respiratory tract infection, compared with 170 episodes of diarrhea and 20 episodes of respiratory tract infection among those randomised to stop co-trimoxazole.

Children not taking co-trimoxazole had a diarrhea incidence of 1.96 episodes/person year (95% confidence interval 1.67 to 2.27), whereas those taking co-trimoxazole prophylaxis had a diarrhea incidence of 1.83 episodes/person year (1.57 to 2.10), resulting in a 9% protective efficacy that was not significant (incidence rate ratio 0.91, $P = 0.48$) (fig 3). The incidence of respiratory tract infections was 0.32 episodes/person year.
| Characteristic                     | Co-trimoxazole prophylaxis | P value of difference |
|-----------------------------------|-----------------------------|-----------------------|
|                                   | Continued (n=299)           | Stopped (n=400)       |                      |
| Mean (SD) baseline temperature (°C)| 38.2 (1.0)                 | 38.4 (1.1)            | 0.05                 |
| Geometric mean baseline parasite density (parasites/μL) | 13.47 | 21.10 | 0.02 |
| Gametocytes present at baseline   | 24 (8)                      | 22 (6)                | 0.27                 |

Principal findings

In this study, we found that co-trimoxazole prophylaxis was moderately protective against malaria in HIV exposed children when continued beyond the period of HIV exposure until 2 years of age in an area of high malaria transmission intensity and high prevalence of resistance to antifolate antimalarial drugs. The protective efficacy of co-trimoxazole was lower in the first month after randomisation, but there was not enough power to detect a significant difference between the first month after randomisation and the remainder of the time at risk. Nevertheless, this may indicate a transitional period when children who had stopped taking prophylaxis were still partially protected. Beyond the first month after randomisation, the protective efficacy of co-trimoxazole against malaria was consistent and did not diminish with time or increasing age. Participants who continued co-trimoxazole prophylaxis also had lower parasite densities at the time of malaria diagnosis and a lower prevalence of recurrent parasitaemia by day 28 after diagnosis, suggesting that co-trimoxazole prophylaxis still provided benefit even when children did acquire malaria.

Comparison with other studies

The protective efficacy of co-trimoxazole prophylaxis against malaria in our trial was substantially lower than year (0.22 to 0.45) for participants continuing co-trimoxazole and 0.23 episodes/person year (0.14 to 0.36) for those not taking co-trimoxazole, resulting in a 37% increased risk of respiratory tract infections for continued co-trimoxazole, though not statistically significant (incidence rate ratio 1.37, P=0.27) (fig 3).

Secondary outcomes and adverse events

At the time of their presentation with malaria, participants randomised to continue taking co-trimoxazole had significantly lower baseline temperature and parasite density than the group who stopped co-trimoxazole (table 2). They also showed a non-significant trend of increased clearance of parasites on days 2 and 3 after malaria diagnosis (table 2). Furthermore, the risk of treatment failure (recurrent parasitaemia by day 28 after diagnosis and treatment) was significantly lower among the children who continued co-trimoxazole (19% vs 32%, P=0.006).

There was no difference between the two study arms in either the median haemoglobin concentration at day 0 of each malaria episode or the mean change in haemoglobin concentration between day 0 and day 28 of malaria follow-up. Median neutrophil values and the prevalence of neutropenia from routine complete blood counts were not significantly different between the two study arms. There were no episodes of skin reactions, allergic drug reactions, or other unexpected adverse events in either study arm.
has been reported in other studies. A randomised controlled trial in Mali showed that co-trimoxazole prophylaxis had a 99.5% protective efficacy against episodes of clinical malaria and 97% efficacy against infection. However, the Mali study enrolled older children (5–15 years old), had a three month follow-up period, and did not test the HIV status of the children or their mothers, though the overall prevalence of HIV infection in the Mali study region was <2% compared with 6%–7% in eastern Uganda. Moreover, sulfadoxine-pyrimethamine, a common antifolate antimalarial drug, was quite efficacious against malaria in most of western Africa at that time, although antifolate resistance is now emerging.

An observational study in Tororo, Uganda, showed an 80% decrease in the incidence of malaria among HIV infected adults and children, as well as among the uninfected members of their households, after implementation of co-trimoxazole prophylaxis. A prospective parallel cohort study in Kampala, Uganda, also showed an 80% protective efficacy of co-trimoxazole prophylaxis against malaria among HIV infected children compared with HIV uninfected children not taking co-trimoxazole.

The lower protective efficacy of co-trimoxazole observed in our study may be due to an improved study design compared with most of the other studies (randomised trial vs observational study), but it was also probably influenced by differences in malaria transmission intensity, participants’ HIV status and ages, and prevalence of plasmodial antifolate resistance mutations.

*Episodes in which Plasmodium falciparum genotypes could be established, from a total of 296 randomly selected episodes.

The concern for rebound of malaria incidence after cessation of chemoprophylaxis, Co-trimoxazole prophylaxis may have a logistical advantage over other antimalarial prophylactic drugs since it is already in widespread use among HIV infected and HIV exposed patients in many countries, though the issue of rebound malaria after cessation needs to be investigated.

The protective efficacy of daily co-trimoxazole prophylaxis against malaria in our study was comparable to that reported in trials of the RTS,S/AS01 malaria vaccine and intermittent preventive therapy in infants (IPTi). The IPTi Consortium has completed six clinical trials investigating the use of such therapy with sulfadoxine-pyrimethamine in different settings and showed an average protective efficacy of 30% with three trials, as well as reducing anaemia.

The IPTi trials differ from our trial in that a lower percentage of participants used bed nets, the risk of malaria was substantially lower, and the efficacy of sulfadoxine-pyrimethamine treatment for uncomplicated malaria was greater than 70%. It is likely that the protective efficacy of intermittent preventive therapy with sulfadoxine-pyrimethamine will decrease with increasing antifolate resistance, and a replacement drug has not yet been firmly established.

In our trial co-trimoxazole prophylaxis showed a protective efficacy against malaria of 39%, even in the setting of high antifolate resistance and high malaria risk in Tororo. However, this level of protection from malaria comes at the expense of the increased potential for adverse events, cost, and logistical difficulties of providing daily co-trimoxazole compared with intermittent sulfadoxine-pyrimethamine prescribed at the time of childhood vaccinations.

Antifolate resistance and secondary outcomes

Because of the risk of evidence of cross resistance to co-trimoxazole and sulfadoxine-pyrimethamine, scientists have been concerned that the widespread use of co-trimoxazole prophylaxis will result in an increased prevalence of sulfadoxine-pyrimethamine resistant parasites. Recent studies in Tororo and Kampala, Uganda, of HIV infected children and adults taking daily co-trimoxazole prophylaxis have found no association between co-trimoxazole use and increased prevalence of mutations conferring antifolate resistance. Both studies were limited by a high baseline level of antifolate resistant genotypes and relatively small numbers. In our study, the prevalence of the dhfr/dhps quintuple mutant was similar in the two treatment arms, but our ability to detect an association between co-trimoxazole use and the dhfr/dhps quintuple mutant was limited by the virtual saturation of the quintuple mutant in the parasite population around Tororo. Indeed, to our knowledge, the overall prevalence of the dhfr/dhps quintuple mutant in our study is the highest yet reported in Africa. Although the dhfr/dhps quintuple mutant has been shown to be related to the failure of sulfadoxine-pyrimethamine therapy for uncomplicated malaria,
the role of this mutant in affecting the protective efficacy of co-trimoxazole prophylaxis against malaria has yet to be determined.

HIV exposed children experience increased morbidity and mortality in their first years of life compared with HIV uninfected children born to uninfected mothers \(^3\) \(^5\) \(^6\) \(^9\) \(^2\). The reasons for these poor outcomes among HIV exposed children have been clearly postulated \(^3\) \(^5\) \(^6\) \(^9\) \(^2\) and may explain why co-trimoxazole prophylaxis in this population could provide protection against serious bacterial and parasitic infections. However, although co-trimoxazole prophylaxis was protective against malaria in our cohort, we detected no differences between the two study arms in the rates of either diarrhoea or respiratory tract infections, two common and potentially fatal infectious syndromes associated with HIV infection. The question of whether the benefits of co-trimoxazole prophylaxis among HIV exposed infants who remain HIV uninfected outweigh the risks has yet to be clearly delineated.

Conclusions and policy implications

Our data add to the growing number of malaria chemoprevention trials, which are trying to discern the best drug, dose, treatment frequency, and treatment duration for children living in areas of differing malaria transmission intensities. The primary relevance of our findings is that co-trimoxazole prophylaxis afforded significant protection against malaria in a setting of highly endemic and highly resistant malaria. Currently, co-trimoxazole is used as prophylaxis in HIV exposed children to prevent opportunistic infections such as toxoplasmosis and pneumocystis. Given the increasing interest in chemoprevention of malaria, we looked at continuing co-trimoxazole prophylaxis among those children who did not seroconvert during breastfeeding, and we found that continuing co-trimoxazole helps to prevent malaria in this population. Our study also provides insight into providing malaria chemoprevention to all children, regardless of HIV status or exposure.

It is premature to conclude whether co-trimoxazole should be recommended for HIV exposed children testing HIV negative after cessation of breast feeding.
