Random Beamforming with Heterogeneous Users and Selective Feedback: Individual Sum Rate and Individual Scaling Laws

Yichao Huang, Member, IEEE, and Bhaskar D. Rao, Fellow, IEEE

Abstract

This paper investigates three open problems in random beamforming based communication systems: the scheduling policy with heterogeneous users, the closed form sum rate, and the randomness of multiuser diversity with selective feedback. By employing the cumulative distribution function based scheduling policy, we guarantee fairness among users as well as obtain multiuser diversity gain in the heterogeneous scenario. Under this scheduling framework, the individual sum rate, namely the average rate for a given user multiplied by the number of users, is of interest and analyzed under different feedback schemes. Firstly, under the full feedback scheme, we derive the closed form individual sum rate by employing a decomposition of the probability density function of the selected user’s signal-to-interference-plus-noise ratio. This technique is employed to further obtain a closed form rate approximation with selective feedback in the spatial dimension. The analysis is also extended to random beamforming in a wideband OFDMA system with additional selective feedback in the spectral dimension wherein only the best beams for the best-L resource blocks are fed back. We utilize extreme value theory to examine the randomness of multiuser diversity incurred by selective feedback. Finally, by leveraging the tail equivalence method, the multiplicative effect of selective feedback and random observations is observed to establish the individual rate scaling.

In multi-antenna downlink systems, transmission strategies which require less feedback resources \[1\]–\[4\] to fully utilize multiuser diversity \[5\], \[6\], but with asymptotic sum capacity comparable to dirty paper coding \[7\]–\[11\], are favored. The idea of random beamforming \[12\], which satisfies the two aforementioned features has drawn much interest in recent years \[13\]–\[19\]. In the basic random beamforming strategy suggested in \[12\], the transmitter with \(M\) transmit antennas generates \(M\) random orthonormal beams and requires each user to feedback the SINR experienced by them for each beam. Then the transmitter schedules users for transmission that currently have the best channel for each random beam. Despite the considerable literature on this topic, there are three existing open problems:

1) How to address heterogeneous users with diverse large scale channel effects and the impact on scheduling policy?
2) What is the closed form sum rate by exact performance analysis?
3) What is the effect of selective feedback, both spatial and spectral, on the randomness of multiuser diversity?

The first problem is related to a practical downlink system setting with asymmetrically located users having heterogeneous large scale channel effects. This near-far effect was first treated in \[12\] by observing that the system becomes interference dominated when \(M\) is large enough. In the large \(M\) setting, the authors prove that users are asymptotically equiprobable to be scheduled. However, when \(M\) is finite and not increasing simultaneously with the number of users, the greedy scheduling policy employed in \[12\] can not maintain fairness among users. Also, if a round robin scheduling policy was utilized, fairness can be guaranteed, but no multiuser diversity gain could be achieved for capacity growth. Therefore, an alternate scheduling policy is needed to maintain fairness while exploiting multiuser diversity at the same time. In this paper, the cumulative distribution function (CDF)-based scheduling policy \[20\] is leveraged and analyzed in the random beamforming framework, wherein the user whose rate for a given beam is high

\[1\] We use the term exact to denote results valid for arbitrary but finite number of users as opposed to asymptotic results.
enough but least probable to become higher is selected. Under this scheduling policy, each user can be equivalently viewed as competing with other users with the same CDF, thus making the study of individual user rate more relevant and interesting than that of the sum rate. In this paper, we develop the notion of individual sum rate, which is the individual user rate multiplied by the number of users, in order to demonstrate the multiuser diversity gain with user growth for a given user.

The second problem addresses exact system analysis, namely deriving closed form expression for the sum rate for arbitrary but finite number of users. Note that even with full feedback, wherein each user conveys back the signal-to-interference-plus-noise ratio (SINR) for $M$ beams, the closed form sum rate has not been derived. This is partially due to the complicated form of SINR and its interplay with multiuser diversity. In this work, the problem is tackled and solved by a novel probability density function (PDF) decomposition [21] which decomposes and interprets the selected user’s SINR. In [21], the homogeneous setting is considered and in this paper, the technique is extended to the heterogeneous user setting and the closed form individual sum rate is derived. The closed form result under full feedback helps in evaluating the system performance and acts as the building block for exact analysis with selective feedback.

The third problem is concerned with standard selective feedback in the spatial dimension, wherein each user feeds back the SINR for the best beam among the $M$ beams and the corresponding beam index. This selective feedback is fundamentally different than full feedback in two aspects. The first difference is the two-stage maximization with the first stage maximization carried out by each user for feedback selection and the second stage maximization carried out by the scheduler to perform user selection. Since the best beam is selected by each user, the first stage maximization is over $M$ correlated SINR. This correlation issue has been addressed in [22], [23], and the CDF for the selected SINR at the user side is derived. In this paper, we propose an approximation for the CDF and utilize it to derive closed form rate approximation. The other fundamental difference is the number of the SINR values that the scheduler has to maximize over for each beam. This number is fixed and equals the number of users in the full feedback case. However, with selective feedback, it becomes a random quantity. In other words, selective feedback results in a random effect on the multiuser diversity. This effect was first observed in [22]. In this paper, we investigate the randomness of multiuser diversity by extremes over random samples and provide a rigorous argument on the rate scaling.
The third problem is further extended to include spectral selectivity by examining a wideband OFDMA system, which groups the subcarriers into resource blocks [24] to form the basic scheduling and feedback unit. In order to save feedback resource while not significantly degrading the system performance, additional selective feedback in the spectral dimension is necessary. The effect of random beamforming in a wideband system is examined in [25] by extensive simulations, and further studied from a utility function perspective with the proportional-fair scheduler in [26]. In [27], analytical results on the asymptotic cluster size is provided. Apart from the thresholding-based partial feedback strategy [28], the best-L selective feedback strategy [29] is appealing and utilized in practical systems such as LTE [30]. In this paper, we employ the best-L selective feedback strategy to investigate random beamforming and the effect of spectral dimension selective feedback, which calls for an additional maximization stage at the user side to perform feedback selection. In this feedback strategy, only the best beams from the best L resource blocks along with the beam and resource block index are fed back from each user. In this paper, we first derive a closed form rate approximation with exact analysis, i.e., valid for arbitrary but finite number of users. Then, the influence of the additional spectral dimension selective feedback on the type of convergence is investigated with the technique of tail equivalence. Moreover, the multiplicative effect of selective feedback and random observations is observed to establish the rate scaling.

To summarize, the main contributions of this paper are threefold: the utilization of CDF-based scheduling policy to address heterogeneous users with random beamforming, the obtained closed form rate results with different selective feedback assumptions, and the asymptotic analysis on the randomness of multiuser diversity incurred by selective feedback. These three contributions analytically examine the raised open problems, and foster further understanding on random beamforming with heterogeneous users and selective feedback. The organization of this paper is as follows. Section [II] reviews the basic narrowband system model for random beamforming. The analysis for the full feedback case is carried out in Section [III] and for the spatial dimension selective feedback in Section [IV]. Section [V] provides the model for the wideband OFDMA with random beamforming, and examines the effect of additional spectral dimension selective feedback on rate performance. Finally, Section [VI] concludes the paper.
II. System Model

We consider a multi-antenna narrowband Gaussian downlink channel with \( K \) single antenna receivers and a transmitter equipped with \( M \) antennas. A block fading channel model with coherence interval \( T \) is assumed. The random beamforming strategy employs \( M \) random orthonormal vectors \( \phi_m \in \mathbb{C}^{M \times 1} \) for \( m = 1, \ldots, M \), where the \( \phi_i \)’s are drawn from an isotropic distribution independently every \( T \) channel uses \cite{12}. Denoting \( s_m(t) \) as the \( m \)th transmission symbol at time \( t \), the transmitted vector of symbols at time \( t \), represented by \( s(t) \in \mathbb{C}^{M \times 1} \), is given as

\[
\mathbf{s}(t) = \sum_{m=1}^{M} \phi_m(t) s_m(t), \quad t = 1, \ldots, T.
\]  

(1)

Let \( y_k(t) \) be the received signal at the \( k \)th user, then

\[
y_k(t) = \sum_{m=1}^{M} \sqrt{\rho_k} h_k^\dagger(t) \phi_m(t) s_m(t) + v_k(t),
\]

(2)

where \( h_k \in \mathbb{C}^{M \times 1} \) is the complex channel vector which is assumed to be known at the receiver, \( v_k \) is the additive white noise, and the elements of \( h_k \) and \( v_k \) are i.i.d. complex Gaussian with zero mean and unit variance \( \mathcal{CN}(0, 1) \). Note that this channel assumption corresponds to the Rayleigh fading assumption for the small scale channel effect. From now on, the time variable \( t \) will be dropped for notational convenience. The total transmit power is chosen to be 1, i.e., \( \mathbb{E}[s^\dagger s] = 1 \), and thus the received signal-to-noise ratio (SNR) of user \( k \) is \( \rho_k \). In a practical downlink setting, due to different locations of users, the large scale channel effects \( \rho_k \) which may consist of path loss and shadowing vary across users. From (2), the SINR of the \( k \)th user for the \( m \)th transmit beam can be computed as

\[
\text{SINR}_{k,m} = \frac{|h_k^\dagger \phi_m|^2}{M/\rho_k + \sum_{i \neq m} |h_k^\dagger \phi_i|^2}, \quad m = 1, \ldots, M.
\]  

(3)

Denote \( Z_{k,m} \triangleq \text{SINR}_{k,m} \) for notational simplicity. Then for a given beam \( m \), the \( Z_{k,m} \)’s are independent across users \( k \) but non-identically distributed due to different \( \rho_k \). For a given user \( k \), the \( Z_{k,m} \)’s are identically distributed and correlated. Thus the beam index \( m \) can be dropped in the expression for the PDF, which is computed in \cite{12} as

\[
f_{Z_k}(x) = e^{-\frac{M}{\rho_k} x} \frac{1}{(1 + x)^M} \left( \frac{M}{\rho_k} (1 + x) + M - 1 \right) u(x),
\]  

(4)
where \( u(\cdot) \) is the Heaviside step function. The CDF of \( Z_k \) is shown in [12] to be

\[
F_{Z_k}(x) = \left( 1 - \frac{e^{-\frac{M}{\alpha_k}x}}{(1+x)^{M-1}} \right) u(x). \tag{5}
\]

### III. FULL FEEDBACK ANALYSIS

This section is devoted to the analysis for the full feedback case wherein each user feeds back the SINR for \( M \) beams. Since under full feedback, all the beams are fed back, the order statistics for each beam is over \( K \) independent random variables. Thus this case is well suited for illustration of the scheduling policy and the derivation of the individual sum rate.

#### A. Scheduling Policy and Individual Sum Rate

After receiving the SINR\(_{k,m}\) from user \( k \) for beam \( m \), the scheduler is ready to perform user selection. In a homogeneous setting, selecting the user with the largest SINR for a given beam maintains fairness and obtains multiuser diversity gain. This system was analyzed in our recent work [21]. The work is now expanded to the more complex heterogeneous case. In a heterogeneous setting, the greedy scheduling policy would be highly unfair for finite \( M \). The round robin scheduling policy can maintain scheduling fairness, but no multiuser diversity gain can be obtained. The proportional-fair scheduling policy [6], [26] achieves the system fairness in terms of system utility. However, under the scenario of inter-beam interference, the users’ rates are coupled under the proportional-fair scheduling policy. This coupled effect makes it very difficult, if not impossible, to develop further analytical results. Therefore, to tackle this problem it is useful to consider alternate scheduling policies that decouple each user’s rate. In this paper, we employ the CDF-based scheduling policy [20] for further analysis. According to this policy, the scheduler will utilize the distribution of the received SINR, i.e., \( F_{Z_k} \). It is assumed that the scheduler perfectly knows the CDF\(^{\text{3}}\), and it performs the following transformation [20]:

\[
\tilde{Z}_{k,m} = F_{Z_k}(Z_{k,m}). \tag{6}
\]

\(^2\)Note that extensive simulation results have been provided regarding the use of proportional-fair scheduling policy under random beamforming in existing literature such as [26]. However, the coupled effect of user’s rate prevents further analysis and it remains an open problem to theoretically understand the system performance of proportional-fair scheduling policy under the heterogeneous user setting with inter-beam interference.

\(^3\)This is the only system requirement to conduct the CDF-based scheduling, and the CDF can be obtained by infrequent feedback from users and learned by the system.
The transformed random variable $\tilde{Z}_{k,m}$ is uniformly distributed ranging from 0 to 1, and independent and identically distributed (i.i.d.) across users for a given beam. Denote $k_m^*$ as the random variable representing the selected user for beam $m$, then

$$k_m^* = \max_{U_m} \tilde{Z}_{k,m},$$

where $U_m$ denotes the set of users conveying feedback for beam $m$. In the full feedback case, $|U_m| = K$. After user $k_m^*$ is selected per (7), the scheduler utilizes the corresponding $Z_{k_m^*,m}$ for rate matching of the selected user. Let $X_m$ be the SINR of the selected user for beam $m$ and now consider the sum rate of the system defined as follows,

$$R = \mathbb{E} \left[ \sum_{m=1}^{M} \log_2 (1 + X_m) \right].$$

From the aforementioned formulation, the sum rate can be computed in the following procedure

$$R \simeq M \mathbb{E}_{k_m^*} \left[ \int_0^1 \log_2 \left( 1 + \frac{1}{Z_{k_m^*,m}^{-1}}(x) \right) dx \right]$$

$$= \frac{M}{K} \sum_{k=1}^{K} \int_0^{\infty} \log_2(1 + t) d(F_{Z_k}(t)) K = \frac{M}{K} \sum_{k=1}^{K} J_k(K),$$

where (a) follows from the sufficient small probability that multiple beams are assigned to the same user; (b) follows from the change of variable $x = F_{Z_{k_m^*,m}}(t)$, the fair property of the CDF-based scheduling, and the following definition for $J_k(\epsilon)$ with exponent $\epsilon \in \mathbb{N}_+$:

$$J_k(\epsilon) \triangleq \int_0^{\infty} \log_2(1 + x) d(F_{Z_k}(x))^\epsilon.$$  

With the help of the CDF-based scheduling, each user feels as if the other users have the same CDF for scheduling competition [20]. Therefore, each user’s rate is independent of other users making it possible to consider or predict individual user’s rate by only examining its own CDF. It is clear that the scheduling policy is not only fair, but also acknowledges multiuser diversity at the same time. If we denote the sum rate as the “macro” level understanding of the system performance, then the individual user rate can be seen as the “micro” level understanding of the system performance since this performance metric examines the rate for any specific user and the sum rate can be directly computed from the individual user rate from all the users. Thus, under the CDF-based scheduling policy, each user’s rate can be examined separately and this property serves as one building block for further analysis with selective feedback.
In order to demonstrate the multiuser diversity gain for each individual user, we define the individual sum rate $\hat{R}_k$ for user $k$ which is the individual user rate $R_k$ multiplied by the number of users, as follows

$$\hat{R}_k \triangleq K R_k = M \mathcal{J}_k(K).$$

(11)

The definition of the individual sum rate under the CDF-based scheduling policy makes it natural to examine the rate scaling for each user separately, and also provide a “micro” level understanding of the sum rate scaling. Compared with the sum rate and the individual user rate which can be treated as performance metrics, the notion of individual sum rate can be regarded as the analytic metric for further scaling analysis.

Note that in the homogeneous setting, $\mathcal{J}_k(\epsilon)$ reduces to $\mathcal{J}(\epsilon) \triangleq \int_0^\infty \log_2(1 + x)d(F_Z(x))'$. It is mentioned in previous works that the exact closed form for $\mathcal{J}(\epsilon)$ is hard to obtain due to the coupled effect of SINR and multiuser scheduling. In the sequel, the closed form expression for $\mathcal{J}_k(\epsilon)$ is obtained which is the key to computing the sum rate given by (9). The main technique is employing the following proposed PDF decomposition which readily follows from [21].

Lemma 1. (PDF Decomposition) $d(F_{Z_k}(x))'$ can be decomposed as

$$d(F_{Z_k}(x))' = \frac{\epsilon}{(1 + x)^{M-1}} \int_0^\infty \frac{e^{\frac{M(i+1)x}{\rho_k}}}{(1 + x)^{M-1}(i+1)} I(\alpha, \beta) \,dx.$$  

(12)

With the help of this PDF decomposition, $\mathcal{J}_k(\epsilon)$ can be computed in closed form using standard integration techniques whose expression is presented in the following theorem.

Theorem 1. (Closed Form of $\mathcal{J}_k$)

$$\mathcal{J}_k(\epsilon) = \frac{\epsilon}{\ln 2} \sum_{i=0}^{\epsilon-1} \binom{\epsilon - 1}{i} \frac{(-1)^i}{i+1} \mathcal{I} \left( \frac{M(i + 1)}{\rho_k}, (M - 1)(i + 1) + 1 \right),$$

(13)

where $\mathcal{I}(\alpha, \beta) \triangleq \int_0^\infty \frac{e^{-\alpha x}}{(1+x)^{\beta}} \, dx$ whose closed form expression is presented in Appendix A.

Proof: The proof is given in Appendix A.

Remark: A few remarks are in order. Firstly, the analytically useful PDF decomposition decouples the effect of multiuser diversity and random beamforming, which facilitates the integration. The decomposition is general in that it can be applied to other channel models, though in this paper the simple Rayleigh channel model is assumed to obtain the SINR statistics in (5). Secondly, the derived closed from results for the individual sum rate and the sum rate
only involve finite sums and factorials, which can readily be computed. Moreover, the derived \( \mathcal{J}_k(\epsilon) \) will be employed as a building block for rate computation in Section IV and Section V with selective feedback.

### B. Individual Scaling Laws

With homogeneous setting, the asymptotic sum rate scaling is of interest and has been established as \( M \log_2 \log_2 K \) \cite{ref12} given the SINR statistics in (5). It can be easily seen that the multiuser diversity gain is linear with respect to the number of transmit antennas. With heterogeneous setting employing the CDF-based scheduling, the same technique can be applied to obtain the asymptotic scaling for the individual sum rate \( \hat{R}_k \) of user \( k \). We now develop the notion of individual rate scaling and state the individual scaling laws under full feedback through the following theorem.

**Theorem 2. (Individual Scaling Laws Under Full Feedback)**

\[
\lim_{{K \to \infty}} \frac{\hat{R}_k}{M \log_2 \log_2 K} = 1. \tag{14}
\]

**Remark:** It is seen from Theorem 2 that users asymptotically follow the same scaling laws in the CDF-based scheduling policy. The large scale channel effect \( \rho_k \) is not written explicitly in (14) since it is a constant inside the log term. It should briefly be noted that the rate scaling only measures the asymptotic trend when \( K \to \infty \) and thus can not accurately match the exact performance for finite regions of \( K \).

### IV. Selective Feedback in the Spatial Dimension

This section examines selective feedback in the spatial dimension wherein each user only conveys the best beam. This standard user side selection requires the handling of correlated random variables and the random effect on observations, which are pursued in Section IV-A and Section IV-B.

#### A. Individual Sum Rate

With selective feedback, each user selects and feeds back the largest SINR among \( M \) beams. As discussed in Section II, the \( Z_{k,m} \)'s are correlated random variables given \( k \). Thus simple order statistics result can not be used to characterize the selected SINR at user side. Denote
Following the derivation in Section III-A, let

\[
F_{Y_{k,m^*(k)}}(x) = \left(1 - \sum_{i=1}^{M} \frac{[d_i(x)]_+ e^{-\frac{2M_x}{A_i(x)}}}{A_i(x)} \right) u(x),
\]

(15)

where \(d_i(x) = \frac{2(1-(M-i)x)}{M-i+1}\), \(A_i(x) = d_i(x) \prod_{i \neq i}(d_i(x) - d_i(x))\), and \([.]+\) is the positive part of the argument. Note that the distribution does not depend on the selected beam index \(m^*(k)\) due to the identically distributed property across beams and is dropped to simplify notation, i.e., \(F_{Y_{k,m^*(k)}}(x) = F_{Y_k}(x)\). Using a similar procedure to that described in Section III-A, after receiving feedback, the scheduler performs the transformation for user selection:

\[
\tilde{Y}_{k,m^*(k)} = F_{Y_k}(Y_{k,m^*(k)}).
\]

(16)

Compared with (6), it is clear that \(F_{Y_k} = F_{Z_k}\) for the full feedback case. Denote \(k^*_m\) as the random variable representing the selected user for beam \(m\), then

\[
k^*_m = \max_{U_m} \tilde{Y}_{k,m^*(k)},
\]

(17)

where \(U_m = \{k : m^*(k) = m\}\) denotes the set of users conveying feedback for beam \(m\). \(U_m\) is a set of random size and the probability mass function (PMF) can be shown to be given by

\[
\mathbb{P}(|U_m| = \tau_1) = \binom{K}{\tau_1} \left( \frac{1}{M} \right)^{\tau_1} \left( 1 - \frac{1}{M} \right)^{K - \tau_1}, \quad 0 \leq \tau_1 \leq K.
\]

(18)

Following the derivation in Section III-A, let \(X_m\) be the selected SINR for beam \(m\) at the scheduler side, then conditioned on \(k^*_m\) and \(|U_m| = \tau_1\), the conditional CDF of \(X_m\) can be written as \(F_{X_m|k^*_m,|U_m|=\tau_1}(x) = (F_{Y_{k^*_m,m}}(x))^{\tau_1}\). By averaging over the randomness of \(|U_m|\), the conditional CDF is expressed as

\[
F_{X_m|k^*_m}(x) = \sum_{\tau_1=0}^{K} \binom{K}{\tau_1} \left( \frac{1}{M} \right)^{\tau_1} \left( 1 - \frac{1}{M} \right)^{K - \tau_1} (F_{Y_{k^*_m,m}}(x))^{\tau_1}.
\]

(19)

From (9) and (11), the individual sum rate of user \(k\) is derived as

\[
\hat{R}_k = M \sum_{\tau_1=1}^{K} \binom{K}{\tau_1} \left( \frac{1}{M} \right)^{\tau_1} \left( 1 - \frac{1}{M} \right)^{K - \tau_1} \int_0^{\infty} \log_2(1 + x) d(F_{Y_k}(x))^{\tau_1}.
\]

(20)

\(^4\)In this paper, it is assumed that if no user feeds back SINR for a certain beam, that beam would be in scheduling outage and would not contribute to rate calculation.
Fig. 1. Comparison of the exact CDF $F_{Y_k}$ with the Fréchet upper bound and the negative association upper bound for spatial dimension selective feedback ($M = 4$, $\rho_k = 10$ dB).

Due to the complicated form of $F_{Y_k}$, the exact closed form expression for (20) is hard to obtain. We now aim to provide an approximate expression for the closed form by examining the property of $F_{Y_k}$ and utilizing the established result in Section III-A. Recall that $Y_k$ is the maximization over $M$ correlated random variables $Z_{k,m}$, thus alternative approximation for $F_{Y_k}$ would lead to rate approximation. One simple approach is to use the Fréchet upper bound [31] for the $Z_{k,m}$’s. Since the $Z_{k,m}$’s are identically distributed across $m$, the Fréchet upper bound yields $F_{Z_k}$. This upper bound is very loose empirically for $F_{Y_k}$. One suitable approach is inspired by the conjectured negative associated upper bound proposed in [22] to deal with the minimum mean square error (MMSE) receiver. Our empirical evidence shows that even with single antenna receiver, the $Z_{k,m}$’s are negative associated [32], thus the upper bound produced by the negative
association property can be utilized to approximate $F_{Y_k}$, namely

$$F_{Y_k}(x) \simeq (F_{Z_k}(x))^M. \quad (21)$$

Fig. 1 illustrates the bounds and the empirical CDF $F_{Y_k}$ for $M = 4$, $\rho_k = 10$ dB. It can be seen that the proposed upper bound in (21) approximates the exact one in (15) well, especially when the SINR is large. By using the CDF approximation, the individual sum rate can be approximated by a closed form expression presented in the following corollary.

**Corollary 1. (Closed Form Approximation of Individual Sum Rate)**

$$\hat{R}_k \simeq \hat{R}_k^{\text{App}} = M \sum_{\tau_1=1}^{K} \binom{K}{\tau_1} \left( \frac{1}{M} \right)^{\tau_1} \left( 1 - \frac{1}{M} \right)^{K-\tau_1} J_k(M\tau_1). \quad (22)$$

**Proof:** The proof is given in Appendix B.

In order to demonstrate the rate approximation in Corollary 1, we conduct a numerical study in Fig. 2 for different $M$ and $\rho_k$ with respect to the number of users. The exact $\hat{R}_k$ in (20) can be calculated by numerical integration. It is observed that (22) approximates the exact rate very well, which makes the rate approximation valuable due to its efficient computational form.

**B. Individual Scaling Laws**

The difficulty of dealing with rate scaling with selective feedback is two-fold. Firstly, due to selective feedback of the best beam, the number of SINR to maximize over at the scheduler side for each beam is a random quantity. This random effect is reflected in the random set $U_m$ in Section IV-A. Secondly, the normalizing constants for establishing the type of convergence [31], [33] have to be obtained for a quantity $\vartheta$ other than the number of users $K$ in the full feedback case. In [22], the first issue was tackled by the Delta method. In this paper, we solve the first issue by referring to the extremes over random samples, and rigorously solve the second one by using the normalizing constants theorem. The proof is provided in Appendix B.

To examine the random effect on multiuser diversity, denote the sequence of random variables $\kappa_m(K)$ as the number of SINR fed back for beam $m$ with $K$ users. It is easy to see that $\kappa_m(K)$ are binomial distributed with probability of success $\frac{1}{M}$. Thus by the strong law of large numbers, as $K$ grows, the number of SINR fed back for each beam becomes $\frac{K}{M}$. The following theorem is called upon to deal with this random effect.
Fig. 2. Comparison of the exact individual sum rate and the approximated one for a given user with different $M$ and $\rho_k$ with respect to the number of users ($M = 2, 4, \rho_k = 0 \text{ dB}, 10 \text{ dB}, 20 \text{ dB}$).

**Theorem 3. (Extremes with Random Sample Size [31], [34])** Let, as $K \to \infty$, $\frac{\kappa(K)}{K} \to \vartheta$ in probability, where $\vartheta$ is a positive random variable. Assume that there are sequences $a_K \in \mathbb{R}, b_K > 0$ such that $\frac{\Lambda K - a K}{b K}$ converges weakly to a nondegenerate distribution function $G$. Then, as $K \to \infty$,

$$
\lim \mathbb{P} \left( \Lambda_{K; \kappa(K)} < a_K + b_K x \right) = \int_{-\infty}^{\infty} G^y(x) d\mathbb{P}(\vartheta < y).
$$

(23)

Therefore, if we denote $\Lambda_{k; \kappa(K)}$ as the extreme order statistics of the received SINR for each beam of a given user $k$, then from Theorem 3 its CDF can be efficiently approximated by $(F_{Y_k})^{K/M}$. Combining this with the normalizing constants theorem in Appendix E yields the following corollary.
Corollary 2. (Individual Scaling Laws Under Spatial Dimension Selective Feedback)

\[
\lim_{K \to \infty} \frac{\hat{R}_k}{M \log_2 \log_2 \frac{K}{M}} = 1, \quad \lim_{K \to \infty} \frac{\hat{R}_{k, \text{App}}}{M \log_2 \log_2 \frac{K}{M}} = 1.
\]

Proof: The proof is given in Appendix B.

Remark: The scaling for the exact rate \( \hat{R}_k \) and approximated rate \( \hat{R}_{k, \text{App}} \) differs in the factor \( \frac{1}{M} \). The rate scaling for \( \hat{R}_{k, \text{App}} \) does not have this factor because intuitively the exponent \( M \) in the approximated CDF \( (F_{Z_k}(x))^M \) counteracts the reduction in the number of SINR values for maximization, i.e., \( \frac{K}{M} \), due to selective feedback. We call this effect as the multiplicative effect. The detailed proof can be found in Appendix B. To draw further insights, we can think of the exponent of \( F_{Z_k}(x) \) as the virtual users. In the full feedback case, the exponent equals \( K \). In the selective feedback case with the approximated CDF, the exponent asymptotically equals \( K \) by the aforementioned multiplicative effect\(^5\). The notion of virtual users and the multiplicative effect will be investigated further with both spatial and spectral dimension selective feedback in Section V-C.

V. Selective Feedback in Both Spatial and Spectral Dimension

In this section, random beamforming is embedded in a wideband OFDMA system. The system model is presented in Section V-A, the exact analysis and the asymptotic analysis are examined in Section V-B and Section V-C respectively.

A. System Model

The system model described in Section II is extended to an OFDMA system with \( N \) resource blocks. Each resource block is regarded as the basic scheduling and feedback unit. The random beamforming strategy generates \( M \) orthonormal beams \( \phi_{m,n} \) for each resource block. Denote \( s_{m,n} \) as the \( m \)th transmission symbol at resource block \( n \), then the received signal \( y_{k,n} \) for user \( k \) at resource block \( n \) can be expressed as

\[
y_{k,n} = \sum_{m=1}^{M} \sqrt{\rho_k} H_{k,n}^\dagger \phi_{m,n} s_{m,n} + v_{k,n},
\]

\(^5\)Note that even though the scaling laws are the same for the full feedback and the selective feedback case, this metric only measures the asymptotic performance when \( K \) is large. The exact rate performance is different due to the randomness of multiuser diversity and the scheduling outage event.
Fig. 3. Illustration of the spatial and spectral dimension selective feedback and the scheduling result in an OFDMA system (different colors denote different users $K = 9$, $N = 5$ resource blocks, $M = 4$ beams, the spectral dimension selective feedback $L = 2$).

where $H_{k,n} \in \mathbb{C}^{M \times 1}$ is the frequency domain channel transfer function of user $k$ at resource block $n$ with i.i.d. $\mathcal{CN}(0, 1)$ elements. To facilitate analysis, $H_{k,n}$ is assumed to be i.i.d. across resource blocks for a given user. This corresponds to the widely used block fading approximation in the frequency domain [35], [36] due to its simplicity and capability to provide a good approximation to actual physical channels. The transmit power for a resource block is assumed to be 1. From (25), the SINR$_{k,n,m}$ of user $k$ at resource block $n$ for beam $m$ is $\text{SINR}_{k,n,m} = \frac{|H_{k,n}^\dagger \phi_{m,n}|^2}{\frac{\rho_k}{M} + \sum_{i \neq m} |H_{k,n}^\dagger \phi_{i,n}|^2}$, and is denoted by $Z_{k,n,m}$ for notational simplicity. For a given user $k$, the $Z_{k,n,m}$’s are i.i.d. across resource blocks for a given beam $m$, and for a given resource block $n$, the $Z_{k,n,m}$’s are identically distributed and correlated across beams. The CDF of $Z_{k,n,m}$ is given by $F_{Z_k}(x) = \left(1 - \frac{M^e}{(1+x)^{M-1}}\right) u(x)$, where the index $n$ and $m$ can be dropped due to the identically distributed property.
B. Individual Sum Rate

With the extra degrees of freedom in the spectral dimension, additional selective feedback at each user side can be made possible by the following two-stage feedback selection. The first stage selection is in the spatial dimension, where each user selects the best beam with the largest SINR for each of the resource block. This process is similar to the narrowband feedback selection discussed in Section IV-A. Let $Y_{k,n,m}$ be the outcome of the first stage selection, thus from (15), its CDF can be written as

$$F_{Y_k}(x) = 1 - \sum_{i=1}^{M} d_i(x) \frac{e^{-2\beta dx_i(x)}}{A_i(x)} u(x),$$

where again the resource block index $n$ and the beam index $m$ can be dropped due to the identically distributed property across resource blocks and beams. The second stage selection occurs in the spectral dimension, where each user feeds back the SINR values of the best $L$ resource blocks among the total $N$ resource blocks. Let $W_{k,n,m}$ denote the outcome of the second stage selection of user $k$ at resource block $n$ for beam $m$. Thus this random variable represents the selected SINR at the user side, whose CDF is of interest for further analysis. It is easy to see that for the case of full feedback in the spectral dimension, i.e., $L = N$, $F_{W_k} = F_{Y_k}$. For the best-1 feedback case, i.e., $L = 1$, $F_{W_k} = (F_{Y_k})^N$ due to the independent property of $Y_k$ across resource blocks. For the general best-L feedback case, utilizing the results in [29], the CDF can be shown as

$$F_{W_k}(x) = \sum_{\ell=0}^{L-1} \xi_1(N, L, \ell)(F_{Y_k}(x))^{N-\ell},$$

where $\xi_1(N, L, \ell) = \sum_{i=L-1}^{\ell} \binom{N}{i} \binom{L}{\ell} (-1)^{i-\ell}$. The two-stage feedback selection is demonstrated in Fig. 3 with nine users denoted by different colors, five resource blocks, and four beams. In the illustrated example, we use best-2 spectral dimension feedback, i.e., $L = 2$.

After receiving feedback, the scheduler performs the CDF-based scheduling by first conducting the transformation on the received SINR,

$$\tilde{W}_{k,n,m} = F_{W_k}(W_{k,n,m}).$$

Denote $k^*_{n,m}$ as the random variable representing the selected user at resource block $n$ for beam $m$, then

$$k^*_{n,m} = \max_{U_{n,m}} \tilde{W}_{k,n,m},$$

where $U_{n,m}$ denotes the set of users conveying feedback for beam $m$ at resource block $n$. Following the derivation in Section IV-A let $X_{n,m}$ be the selected SINR for beam $m$ at resource
block \( n \) at the scheduler side. Then averaging over the randomness of \(|U_{n,m}|\), the conditional CDF conditioned on \( k_{n,m}^* \) can be written as

\[
F_{X_{n,m}\mid k_{n,m}^*}(x) = \sum_{\tau_1=0}^{K} \left( \frac{K}{\tau_1} \right) \left( \frac{1}{M} \right)^{\tau_1} \left( 1 - \frac{1}{M} \right)^{K-\tau_1} \sum_{\tau_2=0}^{\tau_1} \left( \frac{\tau_1}{\tau_2} \right) \left( \frac{L}{N} \right)^{\tau_2} \left( 1 - \frac{L}{N} \right)^{\tau_1-\tau_2} (F_{W_{n,m,n,m}}(x))^{\tau_2}. \tag{29}
\]

For further derivation, \((F_{W_k}(x))^{\tau_2}\) is manipulated into the following form by the power series expansion \[29], \[37]:

\[
(F_{W_k}(x))^{\tau_2} = \sum_{\ell=0}^{\tau_2(\ell-1)} \xi_2(N, L, \tau_2, \ell)(F_{Y_k}(x))^{N\tau_2-\ell}, \tag{30}
\]

where

\[
\xi_2(N, L, \tau_2, \ell) = \begin{cases} 
(\xi_1(N, L, 0))^{\tau_2}, & \ell = 0 \\
\frac{1}{\xi_1(N, L, 0)} \sum_{i=1}^{\min(\ell, L-1)} ((\tau_2 + 1)i - \ell) \\
\times \xi_1(N, L, i) \xi_2(N, L, \tau_2, \ell - i), & 1 \leq \ell < \tau_2(L-1) \\
(\xi_1(N, L, L-1))^{\tau_2}, & \ell = \tau_2(L-1).
\end{cases} \tag{31}
\]

Following the same procedure as in Section \[IV-A\] the individual sum rate for user \( k \) can be derived as

\[
\hat{R}_k = \frac{1}{N} \sum_{n=1}^{N} \mathbb{E} \left[ \sum_{m=1}^{M} \log_2 \left( 1 + X_{n,m\mid k_{n,m}^* = k} \right) \right] \\
= M \sum_{\tau_1=1}^{K} \left( \frac{K}{\tau_1} \right) \left( \frac{1}{M} \right)^{\tau_1} \left( 1 - \frac{1}{M} \right)^{K-\tau_1} \sum_{\tau_2=1}^{\tau_1} \left( \frac{\tau_1}{\tau_2} \right) \left( \frac{L}{N} \right)^{\tau_2} \left( 1 - \frac{L}{N} \right)^{\tau_1-\tau_2} \\
\times \sum_{\ell=0}^{\tau_2(L-1)} \xi_2(N, L, \tau_2, \ell) \int_{0}^{\infty} \log_2(1+x)d(F_{Y_k}(x))^{N\tau_2-\ell}. \tag{32}
\]

In order to obtain the closed form rate approximation for \( \hat{R}_k \), the CDF approximation proposed in \( 21 \) by the negative association property is utilized to approximate \( F_{Y_k} \). The closed form result is presented in the following corollary.

**Corollary 3.** (Closed Form Approximation of Individual Sum Rate)

\[
\hat{R}_k \simeq \hat{R}_k^{\text{App}} = M \sum_{\tau_1=1}^{K} \left( \frac{K}{\tau_1} \right) \left( \frac{1}{M} \right)^{\tau_1} \left( 1 - \frac{1}{M} \right)^{K-\tau_1} \sum_{\tau_2=1}^{\tau_1} \left( \frac{\tau_1}{\tau_2} \right) \left( \frac{L}{N} \right)^{\tau_2} \left( 1 - \frac{L}{N} \right)^{\tau_1-\tau_2} \\
\times \sum_{\ell=0}^{\tau_2(L-1)} \xi_2(N, L, \tau_2, \ell)J_k(M(N\tau_2-\ell)). \tag{33}
\]
To understand the impact of spectral dimension selective feedback, we conduct a numerical study assuming $N = 10$, $M = 4$. Fig. 4 plots the exact and approximated rate for different $L$ under $\rho_k = 10$ dB with respect to the number of users. It can be seen that when the number of users is small, there is a certain rate gap between selective feedback and full feedback. However, the gap becomes negligible when the number of users increases. In Fig. 5, the performance is observed for different $\rho_k$ for $K = 20$. From the two figures, we can see that the proposed rate approximation tracks the exact performance very well.

C. Individual Scaling Laws

We now examine the rate scaling with selective feedback in both spatial and spectral dimension. In Section IV-B with spatial dimension selective feedback, the CDF of interest is $F_{Y_k}$ and the

![Diagram](image.png)

Fig. 4. Comparison of the exact individual sum rate and the approximated one for a given user with different spectral dimension selective feedback $L$ with respect to the number of users ($M = 4$, $N = 10$, $\rho_k = 10$ dB, $L = 1, 2, 4, 10$).
number of SINR to maximize over at the scheduler side for each beam approaches $\frac{K}{M}$. With additional spectral dimension feedback, the CDF of $F_{W_k}$ is of primary interest. To get a handle on the randomness of multiuser diversity for this case, an approach similar to that in Section IV-B can be utilized. Let the sequence of random variables $\kappa_{n,m}(K)$ be the number of SINR values fed back for beam $m$ at resource block $n$ with $K$ users. It is easy to see that $\kappa_{n,m}(K)$ are binomial distributed with probability of success $\frac{L}{MN}$. Therefore, by the strong law of large numbers, as $K$ grows, the number of SINR values fed back for each beam at each resource block becomes $\frac{KL}{MN}$. Moreover, the convergence property of the sequence $\kappa_{n,m}(K)$ can be shown by invoking the central limit theorem:

$$
\lim_{K \to \infty} \sqrt{K} \left( \frac{\kappa_{n,m}(K)}{K} - \frac{L}{MN} \right) \overset{d}{\to} \mathcal{N} \left( 0, \frac{L}{MN} \left( 1 - \frac{L}{MN} \right) \right),
$$

(34)
where $d$ indicates convergence in distribution. By applying Theorem \ref{thm:asymp_convergence} the extreme order statistics of the received SINR for each beam at each resource block for a given user $k$ can be efficiently approximated by $(F_{W_k})^{\frac{KL}{MN}}$.

Now the remaining problem is to examine the type of convergence of $F_{W_k}$. Recall the formulation of $F_{W_k}$ as: $F_{W_k}(x) = \sum_{\ell=0}^{L-1} \xi_1(N, L, \ell)(F_{Y_k}(x))^{N-\ell}$. It is known that $F_{Y_k}$ converges weakly to the type 3 Gumbel distribution. Due to the complicated form of $\xi_1(\cdot, \cdot, \cdot)$, it is tedious to directly check the conditions for proving the type of convergence. In order to investigate the tail behavior of $F_{W_k}$ which dominates the type of convergence \cite{3}, the following tail equivalence theorem is called upon.

\textit{Theorem 4. (The Tail Equivalence Theorem \cite{39})} $U(\cdot)$ and $V(\cdot)$ are distribution functions such
that
\[
\lim_{x \to \infty} \frac{1 - U(x)}{1 - V(x)} = 1. \tag{35}
\]
If there exist normalizing constants \(a_K, b_K > 0\) such that \(U^K(a_K + b_K x) \to G(x)\), where \(G(x)\) is non-degenerate, then \(V^K(a_K + b_K x) \to G(x)\).

From Theorem 4 one can infer that if two distribution functions are tail equivalent, then they belong to the domain of attraction of the same type. Employing Theorem 4, a tail equivalent formulation can be obtained for \(F_{W_k}\) expressed in the following corollary.

**Corollary 4.** *(Tail Equivalent CDF)* \(F_{W_k}(x)\) is tail equivalent to \((F_{Y_k}(x))^{N - \sum_{\ell=0}^{L-1} \xi_1(N,L,\ell) L}\).

**Proof:** The proof is given in Appendix C

Fig. 6 compares the exact CDF and the corresponding tail equivalence for different selective feedback \(L\) under \(M = 4, N = 10\), and \(\rho_k = 10\) dB. The tail equivalent CDF is observed to track the exact one even when \(x\) is small, which supports and lends confidence in the power of the tail equivalence theorem. Therefore, the tail equivalence is used to study the type of convergence, which is expressed in the following lemma.

**Lemma 2.** *(Type of Convergence of Selective Feedback)* Given the statistical property of \(F_{Y_k}\) in (15), \(F_{W_k}\) belongs to the domain of attraction of type 3 Gumbel distribution.

**Proof:** The proof is given in Appendix C

Having obtained the type of convergence for \(F_{W_k}\), the rate scaling result can be derived by referring to the normalizing constants theorem in Appendix B. The individual rate scaling is provided below.

**Theorem 5.** *(Individual Scaling Laws Under Spatial and Spectral Dimension Selective Feedback)*

\[
\lim_{K \to \infty} \frac{\hat{R}_k}{M \log_2 \log_2 \frac{(N - \sum_{\ell=0}^{L-1} \xi_1(N,L,\ell) L)}{MN}} = 1, \quad \lim_{K \to \infty} \frac{\hat{R}_k^{App}}{M \log_2 \log_2 \frac{(N - \sum_{\ell=0}^{L-1} \xi_1(N,L,\ell) L)}{N}} = 1. \tag{36}
\]

**Proof:** The proof is given in Appendix C

**Remark:** For the exact rate \(\hat{R}_k\), the ultimate equivalent CDF of interest is \(F_{Y_k}\), thus the exponent \((N - \sum_{\ell=0}^{L-1} \xi_1(N,L,\ell) L)/MN\) due to multiplicative effect can be seen as the virtual users for scheduling competition. This exponent is for the general best-L spectral dimension feedback. For the full feedback \(L = N\), since \(\xi_1(N,N,\ell)\) equals 1 for \(\ell = N - 1\) and 0 otherwise,
the CDF becomes $F_{Y_k}^{K}$. For the best-1 feedback $L = 1$, since $\xi_1(N, 1, \ell)$ is 1 for $\ell = 0$ and 0 otherwise, the CDF becomes $F_{Y_k}^{K}$. Intuitively, the best-1 feedback is asymptotically optimal due to the same number of virtual users. In other words, even though additional maximization reduces the average number of variables for feedback, it counteracts this reduction by increasing the exponent of the CDF. The number of virtual users is the limiting factor that dominates rate scaling. For the approximated rate $\hat{R}_{k}^{\text{App}}$, since the approximated CDF compensates for the spatial dimension selection by increasing the exponent, the rate scaling differs by a factor of $M$.

VI. Conclusion

In this paper, an analytical approach is used to investigate the problem of random beamforming with heterogeneous users and selective feedback. The heterogenous user scenario corresponds to the practical scenario of potentially different large scale channel effects for different users. We leverage the CDF-based scheduling policy to decouple each user’s rate and thus theoretically examine the individual user rate. We develop the notion of individual sum rate to analyze the rate scaling for each individual user. We focus our analysis in this work on theoretically understanding the effect of selective feedback in both spatial and spectral dimensions. On the exact analysis part, extensive numerical results show that our approximate expression for the rate under selective feedback is effective and provides an efficient expression for computing the exact rate. On the asymptotic analysis part, we develop the notion of virtual users and the multiplicative effect to explain the impact of selective feedback on rate scaling. We further discover that the limiting factor for the rate scaling is the exponent for the ultimate CDF of the selected SINR at the scheduler side. The extension of this work from single antenna users to multiple antenna users and more generally the investigation of a multicell MIMO setup with advanced receiver design will be the subject of our future work.

APPENDIX A

Proof of Theorem [7]: With the help of Lemma [1], $\mathcal{J}_k(\epsilon)$ can be computed as

$$
\mathcal{J}_k(\epsilon) = \frac{\epsilon}{\ln 2} \sum_{i=0}^{\epsilon-1} \frac{(-1)^i}{i+1} \int_0^\infty \ln(1+x) \, d \left( 1 - e^{-\frac{M(i+1)x^{(M-1)(i+1)}}{\rho_k}} \right) dx,
$$

(37)
where (a) follows from applying Lemma [1] (b) follows from integration by parts. The closed form result for \( \mathcal{I}(\alpha, \beta) \) in Theorem [1] can be computed in a recursive manner [37] and is presented as follows

\[
\mathcal{I}(\alpha, \beta) = \left\{ \frac{(-1)^{\beta-1} \alpha^{\beta-1} e^{\alpha} E_1(\alpha)}{(\beta-1)!} + \sum_{i=1}^{\beta-1} \frac{(i-1)!}{(\beta-1)!} (-1)^{\beta-i-1} \alpha^{\beta-i-1}, \quad \beta \geq 2 \right. \\
+ \left. e^\alpha E_1(\alpha) \right\} \beta = 1
\]

where \( E_1(x) = \int_x^\infty \frac{e^{-t}}{t} \, dt \) is the exponential integral function of the first order [39].

**APPENDIX B**

**Proof of Corollary [1]**

\[
\hat{R}^{\text{App}}_k (a) \equiv M \sum_{\tau_1 = 1}^{K} \left( \frac{K}{\tau_1} \right) \left( \frac{1}{M} \right)^{\tau_1} \left( 1 - \frac{1}{M} \right)^{K-\tau_1} \int_0^\infty \log_2(1 + x) d(F_{Z_k}(x))^M \tau_1 \\
= M \sum_{\tau_1 = 1}^{K} \left( \frac{K}{\tau_1} \right) \left( \frac{1}{M} \right)^{\tau_1} \left( 1 - \frac{1}{M} \right)^{K-\tau_1} \mathcal{J}(M \tau_1), \quad (39)
\]

where (a) follows from the CDF approximation in (21); (b) follows from the definition and computation of \( \mathcal{J}(\epsilon) \).

**Proof of Corollary [2]** It is shown in [22] that \( F_{Y_k} \) belongs to the domain of attraction of type 3 Gumbel distribution [33]. Thus if the number of SINR to maximize over for each beam is fixed and equals the number of users \( K \), then the following equation holds: \( \lim_{K \to \infty} (F_{Y_k}(a_{k;K} + b_{k;K} x))^K = \Psi(x) \), where \( \Psi(x) = e^{-e^{-x}} \) is the type 3 Gumbel distribution, \( a_{k;K} \) and \( b_{k;K} \) represent the normalizing constants for user \( k \). From Theorem [3] the number of SINR to maximize over for each beam approaches \( \frac{K}{M} \). Let \( c_{k;K} \) and \( d_{k;K} \) denote the normalizing constants for user \( k \) under the selective feedback case. Then the following equation holds: \( \lim_{K \to \infty} (F_{Y_k}(c_{k;K} + d_{k;K} x))^M = \Psi(x) \).

In order to obtain \( c_{k;K} \) and \( d_{k;K} \), the following theorem is called upon.

**Theorem 6. (The Normalizing Constants Theorem [37])** Let \( F_K(y) \) be a sequence of distribution functions. Let \( a_K, b_K > 0, c_K, \) and \( d_K > 0 \) be sequences of real numbers such that, as \( K \to \infty \),

\[
\lim F_K(a_K + b_K x) = U(x), \quad \lim F_K(c_K + d_K x) = V(x)
\]

(40)

for all continuity points \( x \) of the limits, where \( U(x) \) and \( V(x) \) are nondegenerate distribution functions. Then, as \( K \to \infty \), the limits: \( \lim \frac{d_K}{b_K} = B \neq 0 \), \( \lim \frac{c_K - a_K}{b_K} = A \) are finite, and \( V(x) = U(A + B x) \).
The spatial dimension selective feedback case possesses the following situation in Theorem 4: \( F_K(x) = (F_{Y_k}(x))^K, a_K = a_{k;K}, b_K = b_{k;K}, c_K = c_{k;K}, d_K = d_{k;K}, U(x) = \Psi(x), \) and \( V(x) = (\Psi(x))^M. \) The sequence of \( a_{k;K} \) has been derived in [12] as: \( a_{k;K} = \rho_k \log_2 K - \rho_k (M - 1) \log_2 \log_2 K + o(1). \) A suitable choice of \( b_{k;K} \) for type 3 is \( g_k(b_{k;K}) \), where \( g_k(x) \) is the growth function for user \( k \) defined by \( g_k(x) \triangleq \frac{1 - F_{Z_k}(x)}{f_{Z_k}(x)}. \) Thus a suitable sequence is \( b_{k;K} = \rho_k \) for all \( K. \) Solving \((\Psi(x))^M = \Psi(A + Bx)\) yields \( A = -\log M, B = 1. \) Therefore, by referring to Theorem 4 the normalizing constants can be derived to be: \( c_{k;K} = \rho_k \log_2 \frac{K}{M} - \rho_k (M - 1) \log_2 \log_2 K + o(1), \) and \( d_{k;K} = \rho_k \) for all \( K. \) Then by employing the Corollary A.1. in [12], the individual rate for user \( k, \) namely \( \hat{R}_k \) scales as \( M \log_2 \log_2 \frac{K}{M}. \)

Regarding the approximated rate \( \hat{R}_k^{\text{App}} \), since the approximated CDF by negative association is \((F_{Z_k}(x))^M \) and the number of SINR to maximize over approaches \( \frac{K}{M}, \) we have \( \lim_{K \to \infty} (F_{Z_k}(c_{k;K} + d_{k;K}x))^M = \lim_{K \to \infty} (F_{Z_k}(c_{k;K} + d_{k;K}x))^K = \Psi(x). \) Thus the normalizing constants \( c_{k;K} = a_{k;K}, \) and \( d_{k;K} = b_{k;K}, \) which enables the approximated rate \( \hat{R}_k^{\text{App}} \) to scale as \( M \log_2 \log_2 K. \)

**APPENDIX C**

**Proof of Corollary 4** Given Theorem 4 the following equality holds:

\[
\lim_{x \to \infty} \frac{1 - \sum_{\ell=0}^{L-1} \xi_1(N, L, \ell)(F_{Y_k}(x))^{N-\ell}}{1 - (F_{Y_k}(x))^{N - \sum_{\ell=0}^{L-1} \xi_1(N, L, \ell)}} = (a) \lim_{x \to \infty} \frac{\sum_{\ell=0}^{L-1} \xi_1(N, L, \ell)(N - \ell)(F_{Y_k}(x))^{N-\ell-1}f_{Y_k}(x)}{(N - \sum_{\ell=0}^{L-1} \xi_1(N, L, \ell))(F_{Y_k}(x))^{N - \sum_{\ell=0}^{L-1} \xi_1(N, L, \ell) - 1}f_{Y_k}(x)} = (b) 1, \tag{41}
\]

where (a) follows from the L’Hospital’s rule; (b) follows from the fact that \( \sum_{\ell=0}^{L-1} \xi_1(N, L, \ell) = 1. \)

**Proof of Lemma 2:** \( F_{Y_k} \) with statistics in (15) belongs to the domain of attraction of type 3. It can be shown that for any distribution function \( F(x) \) which converges weakly to the limiting distribution, then its exponent form \( F^e(x) \) has the same type of convergence [31], \( (F_{Y_k}(x))^{N - \sum_{\ell=0}^{L-1} \xi_1(N, L, \ell)} \) belongs to the domain of attraction of type 3. Then by Theorem 4 \( F_{W_k} \) belongs to the domain of attraction of type 3.

**Proof of Theorem 5:** A procedure similar to that used in proving Corollary 2 can be used here. Since the number of SINR to maximize over for each beam at each resource block approaches \( \frac{K}{MN}, \) and \( F_{W_k} \) belongs to the domain of attraction of type 3, the following equation holds:

\[
\lim_{K \to \infty} (F_{W_k}(c_{k;K} + d_{k;K}x)) \frac{K}{MN} = \Psi(x). \]

By referring to the tail equivalence theorem, the equivalent
equation holds: \( \lim_{K \to \infty} \left( F_{\hat{Y}_k}(c_{k;K} + d_{k;K}x) \right)^{KL(N - \sum_{\ell=0}^{L-1} \xi_1(N,L,\ell))} = \Psi(x) \). Applying Theorem 6 yields the normalizing constants: \( c_{k;K} = \rho_k \log_2 \frac{KL(N - \sum_{\ell=0}^{L-1} \xi_1(N,L,\ell))}{MN} \) and \( d_{k;K} = \rho_k \) for all \( K \). Therefore, \( \hat{R}_k \) scales as \( M \log_2 \log_2 K + o(1) \).

For the approximated rate \( \hat{R}_k^{\text{App}} \) using the approximated CDF \( (F_{\hat{Z}_k}(x))^M \) for \( F_{\hat{Y}_k} \), the following equation holds: \( \lim_{K \to \infty} \left( F_{\hat{Z}_k}(c_{k;K} + d_{k;K}x) \right)^{KL(N - \sum_{\ell=0}^{L-1} \xi_1(N,L,\ell))} = \Psi(x) \). Using the same line of arguments, \( \hat{R}_k^{\text{App}} \) scales as \( M \log_2 \log_2 K \).

Yichao Huang (S’10–M’12) received the B.Eng. degree in information engineering with highest honors from the Southeast University, Nanjing, China, in 2008, and the M.S. and Ph.D. degrees in electrical engineering from the University of California, San Diego, La Jolla, in 2010 and 2012, respectively. He then join Qualcomm, Corporate R&D, San Diego, CA.

He interned with Qualcomm, Corporate R&D, San Diego, CA, during summers 2011 and 2012. He was with California Institute for Telecommunications and Information Technology (Calit2), San Diego, CA, during summer 2010. He was a visiting student at the Princeton University, Princeton, NJ, during spring 2012. Mr. Huang received the Microsoft Young Fellow Award in 2007 from Microsoft Research Asia. He received the ECE Department Fellowship from the University of California, San Diego in 2008, and was a finalist of Qualcomm Innovation Fellowship in 2010. His research interests include communication theory, optimization theory, wireless networks, and signal processing for communication systems.

Bhaskar D. Rao (S’80–M’83–SM’91–F’00) received the B.Tech. degree in electronics and electrical communication engineering from the Indian Institute of Technology, Kharagpur, India, in 1979, and the M.Sc. and Ph.D. degrees from the University of Southern California, Los Angeles, in 1981 and 1983, respectively.

Since 1983, he has been with the University of California at San Diego, La Jolla, where he is currently a Professor with the Electrical and Computer Engineering Department. He is the holder of the Ericsson endowed chair in Wireless Access Networks and was the Director of the Center for Wireless Communications (2008–2011). His research interests include digital signal processing, estimation theory, and optimization theory, with applications to digital communications, speech signal processing, and human–computer interactions.

Dr. Rao’s research group has received several paper awards. His paper received the Best Paper Award at the 2000 Speech Coding Workshop and his students have received student paper awards at both the 2005 and 2006 International Conference on Acoustics, Speech, and Signal Processing, as well as the Best Student Paper Award at NIPS 2006. A paper he coauthored with B. Song and R. Cruz received the 2008 Stephen O. Rice Prize Paper Award in the Field of Communications Systems. He was elected to the Fellow grade in 2000 for his contributions in high resolution spectral estimation. He has been a Member of the Statistical Signal and Array Processing technical committee, the Signal Processing Theory and Methods technical committee, and the Communications technical committee of the IEEE Signal Processing Society. He has also served on the editorial board of the EURASIP Signal Processing Journal.
