Abstract

Background: Dengue viral infection is a global health threat without vaccine or specific treatment. The clinical outcome varies from asymptomatic, mild dengue fever (DF) to severe dengue hemorrhagic fever (DHF). While adaptive immune responses were found to be detrimental in the dengue pathogenesis, the roles of earlier innate events remain largely uninvestigated. Invariant natural killer T (iNKT) cells represent innate-like T cells that could dictate subsequent adaptive response but their role in human dengue virus infection is not known. We hypothesized that iNKT cells play a role in human dengue infection.

Methods: Blood samples from a well-characterized cohort of children with DF, DHF, in comparison to non-dengue febrile illness (OFI) and healthy controls at various time points were studied. iNKT cells activation were analyzed by the expression of CD69 by flow cytometry. Their cytokine production was then analyzed after α-GalCer stimulation. Further, the CD1d expression on monocytes, and CD69 expression on conventional T cells were measured.

Results: iNKT cells were activated during acute dengue infection. The level of iNKT cell activation associates with the disease severity. Furthermore, these iNKT cells had altered functional response to subsequent ex vivo stimulation with α-GalCer. Moreover, during acute dengue infection, monocytic CD1d expression was also upregulated and conventional T cells also became activated.

Conclusion: iNKT cells might play an early and critical role in the pathogenesis of severe dengue viral infection in human. Targeting iNKT cells and CD1d serve as a potential therapeutic strategy for severe dengue infection in the future.

Introduction

Public health threat of dengue viral infection is expanding globally and most prominent in tropical and subtropical countries. It is the most significant mosquito- borne viral illness affecting mankind. An estimated 2.5 billion people live in the area at risk resulting in 50 to 390 million dengue infections per year [1–3]. Dengue infection causes significant morbidity, mortality and leads to hospitalization that consume vast amount of health care spending mostly in endemic areas where resource is scarce [1–3]. Currently, there is still no vaccine nor specific treatment, in part due to our incomplete understanding of the disease pathogenesis.

Dengue virus (DV) is a single stranded RNA virus in the Flaviviridae family. Four serotypes of dengue virus are circulating and cause human illness. The transmission from human to human requires Aedes mosquito vectors [4]. Once infected with DV, the clinical manifestation varies widely from asymptomatic infection, undifferentiated febrile illness to a more typical dengue fever (DF) characterized by fever associated with severe headache, myalgia, and bone pain, which are mild and self limited. A small percentage of patients develop a more severe, life threatening dengue hemorrhagic fever (DHF), which could result in dengue shock syndrome (DSS) [1]. The hallmarks of DHF/DSS are plasma leakage and hemorrhage that could lead...
Author Summary

Almost half of the world population is at risk of dengue viral infection. The disease severity varies from mild to a deadly form-which is caused mainly by host overt immune reaction. Earlier studies focused on the disease-causing roles of adaptive immune cells - cells that are highly specific but require time and signal from rapidly activating immune cells to become active. Invariant Natural Killer T (iNKT) cells are unique T cells that get activated rapidly and can control later adaptive response by secreting cytokines. They can be activated by lipid loaded on CD1d, an antigen presenting molecule. However, their role in human dengue infection was not known. Here, we studied iNKT cells from dengue infected children and found that they were activated. Importantly, the more severe the disease, the higher level of iNKT cells activation. Their cytokine patterns also differ from those of healthy donors. Moreover, together with iNKT cells activation, the level of CD1d was higher and T cells became active. Therefore, iNKT cells likely play a role in the pathogenesis of human dengue infection. New drugs targeting iNKT cells might help dampen the disease severity before the adaptive immune cells become too active.

The potential role of iNKT cells in pathogenesis of DV infection has never been investigated in human. Two previous reports showed increased number and recruitment of T cells bearing NK cell markers to skin infected with DV in mouse [44] and marmoset models [45]. However, these reports did not use standard methods to identify iNKT cells, so it is unclear if these cells are truly iNKT cells. The only study of iNKT cells in DV infection was done in experimental marine model [46] and suggested a detrimental role of iNKT cells in severe form of DV infection. However, DV does not naturally infect mice and the use of mouse model to represent DV infection pathogenesis in human remains controversial [47–49]. Therefore, the study of iNKT cells in human patients is needed.

Here, we investigated the potential role of iNKT cells in DV infection in human by examining well-defined clinical samples from a cohort of DV infected children of varying disease severity and at different time points, in comparison to controls. We found that iNKT cells were activated in acute DV infection, and suggesting the involvement of iNKT cells in human severe DV infection. A better understanding of the role of iNKT cells in human DV infection will lead to a better understanding of the intricate control of complex immune responses and immunopathogenesis in dengue infection. Altogether, the advancement in our knowledge will enable the development of novel preventive and therapeutic approaches in the future.

Methods

Ethics statement

Blood samples were collected from healthy controls and 1–15 year-old patients admitted to Khon Kaen and Songkhla hospitals, Thailand, following written parental informed consent. This project was approved by the ethical committees of Khon Kaen hospital, Songkhla hospital and Mahidol University.

Clinical samples

Peripheral blood mononuclear cells (PBMC) were separated from whole blood by Ficoll-Hypaque density gradient centrifugation and kept in liquid nitrogen for subsequent study. Acute dengue infection was determined by dengue gene identification using reverse transcription PCR (RT-PCR) and dengue virus-specific IgM capture ELISA as previously described [50,51]. Dengue disease severity was classified according to the World Health Organization criteria (1997) [5] into dengue fever (DF) and dengue hemorrhagic fever (DHF). Other non-dengue febrile illness (OFI) patients were defined as patients hospitalized with fever without the presence of dengue infection by both RT-PCR and dengue virus-specific IgM capture ELISA.

Blood samples from each patient were collected at different time points during the course of infection. The date were called in relation to the day fever subsided (day of defervescence, day 0) so that “day -1” is one day before the day of defervescence and “week 2” and “month 6” are 2 weeks and 6 months after the day of defervescence, respectively. Random PBMC samples from DF, DHF and OFI were used for analysis in this study.

Samples from 11 DF, 19 DHF, 11 OFI patients and 10 healthy controls were evaluated for percentage and phenotype of peripheral blood iNKT cells. The demographic and clinical characteristics, including age, gender, DV serotype, lowest white blood cells count (WBC), highest hematocrit (Hct), lowest platelet (Plt), highest serum aspartate transaminase (AST), alanine transaminase (ALT) enzyme, and lowest albumin of each patient with DF and DHF are shown in Table S1. A different set of patient samples were used to study the function of iNKT cells by α-β GalCer.
Monocyte CD1d expression

Flow cytometry

Statistical analysis

iNKT cells were activated during acute DV infection and the level of activation associated with dengue disease severity

Results

Demographic and clinical data

The age and gender of patients with DF and DHF in this study were not significantly different. The most common DV serotypes in both groups were DV serotype 1 (DV1), followed by DV2, DV3, and DV4, respectively. As expected, patients with DHF had significantly lower platelet count, serum albumin and higher liver transaminases when compared to those with DF (Table S1 and S2).

The percentage of peripheral blood iNKT cells remain unchanged during the course of DV infection

To examine whether the percentage of iNKT cells changes during the course of DV infection, PBMC from DF and DHF patients were evaluated at 3 different time points (day -1, day 0 and day 2 weeks) as previously described (Figure 1a). Lymphocytes were pregated based on their characteristic appearance on forward and side scattered dot plot. iNKT cells were then identified by the expression of both CD3 and PBS57- loaded CD1d tetramer (as compared to unloaded CD1d tetramer control) (Figure 1a, 2a). The percentage of iNKT cells within total lymphocytes were not significantly changed over the course of DV infection in both patients with DF (Figure 1b, Figure S1a) and DHF (Figure 1c, Figure S1b). When comparing iNKT cells from patients with various severities during febrile phase and controls, the percentage of iNKT cells were also not significantly different between groups of patients (Figure 1d). Absolute number of iNKT cells also showed similar results (Figure S1c-g).

iNKT cells were activated during acute DV infection and the level of activation associated with dengue disease severity

To investigate whether iNKT cells are activated in vivo during human DV infection, peripheral blood iNKT cells from dengue-infected individuals with various disease severities were evaluated at different time points. Expression of CD69 in comparison to isotype control was used as an activation marker of iNKT cells (Figure 2a).

iNKT cells were activated during acute phase (day -1 and day 0) of dengue infection in both DF and DHF patients (Figure 2b). The percentage of CD69 positive iNKT cells was significantly higher during febrile phase (day -1) (median 3.02%; interquartile range 2.18–20.33%) and defervescence phase (day 0) (7.42%; 3.91–13.23%) compared to 2 weeks after fever subsided (0.23%; 0.00–0.51%) (Figure 2e). iNKT cell activation in OFI is higher than in OFI (1.77%; 0.00–7.33%) and healthy controls (0.00%; 0.00–0.51%) (Figure 2e), suggesting that the activation of iNKT cells associated with disease severity. Moreover, iNKT cells were more activated in dengue-infected patients (DF and DHF) than in OFI (1.77%; 0.00–7.33%) and healthy controls (0.00%; 0.00–0.51%) (Figure 2e). iNKT cell activation in OFI is higher than healthy controls (p<0.05), possibly due to the heterogeneous non-dengue infectious etiology of OFI group, some of which could also activate iNKT cells.

Flow cytometry analysis was performed using BD FACS Canto or BD LSRII flow cytometer via FACS Diva version 4.1.1 software. FlowJo version 8.7 (Tree star) was used for data analysis.

Statistical analysis

Data analysis was performed using GraphPad Prism 5.0 software and SPSS version 20. Mann-Whitney test was used for comparison of unpaired data. Wilcoxon signed rank test was used to compare paired data. Spearman’s rho correlation test was used for correlation analysis of non-parametric data. P-value of <0.05 was considered as statistically significant difference.
When cells from each patient were analyzed at 3 different time points, the data clearly showed that the percentage of activated iNKT cells were highest during febrile phase, continuously decreased over the course of infection and barely present by 2 weeks after fever subsided in both patients with DF (Figure 2f) and DHF (Figure 2g). No correlation between iNKT cell activation and DV viral load was observed (data not shown). Therefore, our results showed that iNKT cells were activated during acute dengue infection and the level of activation associated with dengue disease severity.

Peripheral blood iNKT cells from acute DV infected patients had reduced $\alpha$-GalCer mediated production of IFN-$\gamma$.

To study function of the iNKT cells in DV infection, iNKT cells production of various cytokines (IFN-$\gamma$, IL-4 and IL-17) were analyzed by intracellular cytokine staining of gated iNKT cells in comparison to isotype controls. Without stimulation, a small amount of IFN-$\gamma$ and IL-4 could be detected in iNKT cells from some of the acute dengue-infected patients (Figure 3a–b, 3e–f). Previous reports demonstrated that iNKT cells could become anergic or hyporesponsive to $\alpha$-GalCer stimulation if they were previously activated in vivo [52,53]. To further examine the functional properties of the activated iNKT cells from acute DV infected patients, the PBMC were stimulated with $\alpha$-GalCer ex vivo and intracellular cytokines were evaluated. PBMC from DF and DHF patients during acute dengue infection (day 0) were compared to those 6 months after infection, when the immunological effects of acute DV infection were assumed to return to baseline. The results were then compared with unstimulated condition and with PBMC from OFI and healthy subjects (Figure 3).

As expected, after $\alpha$-GalCer stimulation, healthy iNKT cells produced large amount of IFN-$\gamma$ (Figure 3c). In contrast, the capacity to produce IFN-$\gamma$ of iNKT cells from acute DV infected and OFI patients was reduced (Figure 3c, Figure S2a). At day 0, after stimulation, the percentage of IFN-$\gamma^+$ iNKT cells of patients with DF (16.35%; 14.40–24.93%) and DHF (11.95%; 6.77–18.30%) were lower than those of healthy control (32.1%; 25.90–40.70%) (p = 0.002 and p = 0.01, respectively) (Figure 3c). Therefore, the functional change of iNKT cells is not limited to dengue infection but also occur in other febrile illness, again, this could be due to the heterogeneous infectious etiology of OFI. No significant difference between DF and DHF was observed. The responsiveness to $\alpha$-GalCer stimulation returned 6 months after fever subsided to the level similar to those of healthy control (Figure 3d). After $\alpha$-GalCer stimulation, the percentage of IFN-$\gamma^+$ iNKT cells from day 0 were significantly lower than those from 6 months after fever subsided in both patients with DF (day 0: 16.35%; 14.40–24.93% vs. month 6: 29.20%; 19.65–43.00%, p = 0.002) (Figure 3a) and DHF groups (day 0: 11.95%; 6.77–18.30% vs. month 6: 25.65%; 15.35–37.23%, p = 0.01) (Figure 3b). No statistical significant difference was observed when IL-4$^+$ iNKT cells were examined after $\alpha$-GalCer stimulation (Figure 3c–h, Figure S2b).

Interestingly, the iNKT cells cytokine patterns in DF and DHF appears to be different. Acute DF patients have higher IFN-$\gamma$/IL-4 ratio compared to DHF (Figure 3i), suggesting that Th1-like response of iNKT cells in acute DV infection may associate with less disease severity.

IL-17A was not detectable in iNKT cells in all conditions with the current stimulation protocol (data not shown), perhaps because the kinetics of IL-17 is different from IL-4 and IFN-$\gamma$. 

Figure 1. The frequency of peripheral blood iNKT cells during dengue infection with different disease severity. a) Representative dot plots show the percentage of iNKT cells within lymphocytes in healthy, other febrile illness (OFI), dengue fever (DF), and dengue hemorrhagic fever (DHF) at day -1, day 0 and day 2 weeks. b, c) Each dot represents percentage of iNKT cells of each patient in DF (b) and DHF (c) groups at 3 different time points, the line represents median of each group. d) The percentage of iNKT cells during febrile phase (day -1) of healthy, OFI, DF and DHF. Mann-Whitney test (b–d) was used for statistical comparison, p<0.05 was considered as statistically significant difference. No significant difference was found.

doi:10.1371/journal.pntd.0002955.g001
To further examine the kinetics of functional response of iNKT cells to α-GalCer, additional time points at day -1 and week 2 were studied (Figure S3 and S4). The responses at these 2 additional time points were not statistically significant different. However, iNKT cells from DHF at 2 weeks appeared to produce more IFN-γ than at day -1 but due to the limited number of sample, statistical test cannot be performed (Figure S4b). Altogether, the IFN-γ response to α-GalCer seems to reduce during acute DV infection and recover by month 6 after acute DV infection but the rate of recovery may differ between patients.

Taken together, these findings suggested that iNKT cells from acute dengue infected patients were previously activated in vivo and upon restimulation with α-GalCer ex vivo, they have reduced IFN-γ production. Importantly, skewing toward Th1-like cytokine pattern of iNKT cells during acute DV infection may associate with less clinical severity.

**Upregulation of CD1d expression on monocytes during acute DV infection**

Our next question was how iNKT cells get activated during acute DV infection. iNKT cells were known to be activated by cognate recognition of iNKT cell receptor to antigen presented on CD1d. In some circumstances, they can be activated indirectly by cytokines or might require both cognate recognition and cytokine-driven activation [54]. To first investigate if iNKT cells could be activated through the CD1d-dependent pathway, we measured CD1d expression on monocytes from the same patient samples used to study iNKT cells. Monocytes were examined because they...
Figure 3. Cytokines production by iNKT cells from dengue infected patients with and without stimulation with α-GalCer. Each dot represents percentage of interferon gamma (IFN-γ) (a–b) and IL-4 (e–f) iNKT cells from DF (a,e) and DHF (b,f) at day 0 and month 6, with (stimulated) and without (unstimulated) α-GalCer stimulation. At day 0 (c, g, i) and 6 months (d, h, j), percentage of IFN-γ⁺ iNKT cells (c,d), IL-4⁺ iNKT cells (g, h) and IFN-γ/IL-4 ratio (i, j) upon α-GalCer stimulation, comparing cells from healthy, OFI, DF and DHF groups. Mann-Whitney test, were used for statistical comparison, p ≤ 0.05 was considered as statistically significant difference (*p ≤ 0.05, **p ≤ 0.01, ***p ≤ 0.001).

doi:10.1371/journal.pntd.0002955.g003
are abundant antigen presenting cells in peripheral blood, known to be infected by dengue virus both in vivo and in vitro, and also known to activate iNKT cells in other circumstances. Monocytes were first gated (Figure 4a) and the level of CD1d expression on monocytes at different time points was then analyzed in comparison to isotype control in both DF and DHF groups (Figure 4b). Interestingly, the expression of CD1d was highest on monocytes during day -1 and day 0, in both DF (median DMFI 16058; 13304–18998 (day -1) and 15682; 20191 (day 0)) and DHF (17499; 14907–22505 (day -1) and 17991; 15896–21235 (day 0)) patients. The level of CD1d expression decreased significantly by 2 weeks after fever subsided in both DF (10184; 7962–11852 (day -1 vs. 2 weeks), p = 0.002 (day 0 vs. 2 weeks)) and DHF (9645; 8999–12712) (p = 0.008 (day -1 vs. 2 weeks), p = 0.002 (day 0 vs. 2 weeks)) (Figure 4c) to the same level as healthy control (10504; 9704–13541) (Figure 4d). The similar trend is clearly observed when data from the same patients at 3 different time points were analyzed (Figure 4e). Monocytic CD1d expression at 6 months was similar to those at 2 weeks (data not shown). Furthermore, when comparing between patients with different dengue disease severity, the level of monocyte CD1d expression at day -1 was higher in DHF than in healthy control (10504; 9704–13541) (p = 0.01), but not significantly higher than that of DF (p = 0.27) (Figure 4d). Thus, CD1d expression on monocytes was upregulated in acute DV infection. Moreover, the level of CD1d expression on monocytes positively correlates, although weakly, with the level of iNKT cell activation (r = 0.35, p<0.05). The correlation is stronger when the DHF subgroup was analyzed (r = 0.7, p = 0.002) (Figure S5). These results suggested that CD1d was upregulated in monocytes during acute DV infection. However, future experiments are needed to delineate if iNKT cells were actually activated in a CD1d-dependent manner in DV infection.

Cytotoxic T cells were activated in relation to iNKT cell activation

In general, once iNKT cells get activated, they were known to influence adaptive T cell immune response. To investigate if iNKT cells activation were associated with the activation of conventional T cells in DV infection, the percentage of CD8+ and CD4+ T cells as well as their activation state were evaluated in the PBMC samples that were used for iNKT cells studies. Lymphocytes were pregated based on their characteristic appearance on forward and side scattered dot plot. CD8+ and CD4+ conventional T cells were then identified by the expression of CD8 or CD4 together with CD3. CD69 in comparison with isotype control was used as activation marker of both CD4+ and CD8+ T cells (Figure S6a, c).

Similar to iNKT cell activation, conventional CD8+ T cells were activated during acute phase of dengue infection in both DF and DHF patients (Figure 5a,b). The percentage of CD69+CD8+ conventional T cells at day -1 (7.62%; 3.36–10.92) was higher than 2 weeks after fever subsided (0.56%; 0.24–1.48) in patients with DF (p = 0.01) (Figure 5a). In patients with DHF, the percentage of CD69+CD8+ conventional T cells was higher at day -1 (10.35%; 7.99–13.08) and day 0 (2.40%; 0.52–8.71) when compared to 2

![Figure 4: Upregulation of CD1d expression on monocytes during acute DV infection](image-url)
weeks after fever subsided (0.30%; 0.14–0.57) (p<0.0001 and p = 0.0008 respectively) (Figure 5b). Furthermore, during febrile phase, patients with DF (7.62%; 3.36–10.92) and DHF (10.35%; 7.99–13.08) have significantly higher percentage of activated CD8+ T cells when compared to OFI (0.76%; 0.15–1.38), and healthy controls (0.32%; 0.02–0.56) (DF vs OFI, p = 0.01, DF vs healthy, p = 0.005, DHF vs OFI, p<0.0001 and DHF vs healthy, p = 0.0001 respectively). At day -1, the percentage of activated CD8+ T cells of DHF appeared to be higher than DF, but did not reach statistical significance (Figure 5c). This is different from previous reports that showed a higher CD8 activation in DHF compared to DF [55–57], possibly due to the small sample size, high variability of the data and different time point analyzed. When cells from each patient were analyzed at 3 different time points, most of the data showed the percentage of activated CD8+ conventional T cells were highest during febrile phase, continuously decreased over the course of infection and almost absent by 2 weeks after fever subsided in both patients with DF (Figure 5d) and DHF (Figure 5e). The activation of CD8+ conventional T cells correlates with iNKT cell activation (r = 0.56, p<0.01) especially in DHF patients (r = 0.69, p<0.01) (Figure S6b), suggesting that iNKT cell activation may associate with the activation of CD8+ conventional T cells especially in DHF patients.

At the analyzed time point, CD4+ conventional T cells were also activated during acute DV infection but to a lesser extent than CD8+ T cells and were more prominent in DHF patients (Figure 5f–j). In DHF, but not DF patients, CD4+ T cells showed higher activation during day -1 (0.72%; 0.36–1.44) and day 0 (0.38%; 0.11–0.59) when compared to 2 weeks afterward (0.07%; 0.03–0.15) (p<0.0001, p = 0.013) (Figure 5g, j). During day -1, DF and DHF patients showed increased CD4+ T cells activation when compared to healthy controls or OFI (Figure 5h). No significant difference was observed between DF and DHF (Figure 5h), although it appears that only a few DF patients showed increased CD4+ T cell activation (Figure 5h, i). The level of CD4+ T cell activation also weakly correlates with the level of iNKT cells activation (r = 0.41, p<0.01), but the correlation is more prominent in DHF (r = 0.57, p<0.01) (Figure S6d).

**Discussion**

Our finding is the first to show that human iNKT cells are activated during acute dengue viral infection and the level of activation associates with disease severity. The activation subsided by 2 weeks after fever subsided. Furthermore, the activated iNKT cells from acute DV infected patients produced less IFN-γ in

doi:10.1371/journal.pntd.0002955.g005
response to subsequent α-GalCer stimulation 

activated in acute dengue infection. Moreover, CD1d expression experiments are needed to demonstrate how iNKT cells are activation through cognate recognition pathway although further suggests the possible involvement of CD1d on iNKT cell function of iNKT cells during acute DV infection cryopreserved PBMC. Further study is warranted to delineate the vivo intracellular cytokines on iNKT cells from patients without any infection. Unfortunately, we could detect only small amount of DV disease severity. It would be interesting to know the pattern of has higher IFN- a fever subsided. Interestingly, iNKT cells from acute DF patients in vivo, rendering them less responsive to subsequent stimulation ex vivo, while their functional capacity returned 6 months after the fever subsided. Interestingly, iNKT cells from acute DF patients has higher IFN-γ/IL-4 ratio after ex-vivo α-GalCer stimulation than those from acute DHF patients. This finding suggests that cytokines pattern produced by iNKT cells could possibly influence DV disease severity. It would be interesting to know the pattern of cytokine production of iNKT cells in vivo during the actual dengue infection. Unfortunately, we could detect only small amount of intracellular cytokines on iNKT cells from patients without any stimulation, which may be because they secreted most cytokines in vivo or because our detection sensitivity is limited by using cryopreserved PBMC. Further study is warranted to delineate the function of iNKT cells during acute DV infection in vivo.

In parallel with iNKT cell activation during acute DV infection, monocyty CD1d surface expression was upregulated. This finding suggests the possible involvement of CD1d on iNKT cell activation through cognate recognition pathway although further experiments are needed to demonstrate how iNKT cells are activated in acute dengue infection. Moreover, CD1d expression on other antigen presenting cells beside monocytes such as dendritic cells may be interesting to examine. Some viruses such as coxakievirus B3 [59] and hepatitis C virus [60] are known to upregulate CD1d expression and activate iNKT cells while others evade iNKT cell recognition by downregulating CD1d, such as Kaposi sarcoma-associated herpes virus [61], herpes simplex virus type 1 [62], HIV type 1 [63,64] and human papilloma virus [65]. Since viruses do not contain viral lipid antigens, it is postulated that viral infection may alter endogenous lipid presented on CD1d and activate iNKT cells with or without help from cytokines [66,67]. Since viruses do not contain viral lipid antigens, altered endogenous lipid might be presented on CD1d [29]. Indeed, recent data suggested alteration of lipid metabolism in DV infected cells but their importance in iNKT cell activation is not yet known [68]. Other possible mechanism to activate iNKT cells, especially cytokine mediated activation, was not evaluated and warrants further study. Cytokines of special interest include, but not limited to, IL-12, IL-18, IL-1β and IL-23. Further investigation is needed to delineate the detail of how dengue virus upregulates CD1d and how exactly iNKT cell activation was achieved in human DV infection.

Once iNKT cells are activated, they are known to influence other immune cells both in innate response such as NK cells, dendritic cells and in adaptive T cell and B cell responses [11,20]. T cells are very important arm of immune defense against viral infection, but T cell overactivation can lead to immunopathology in dengue infection [69,70]. Our results showed the association between iNKT cells activation, T cell activation and disease severity. Consistently, in murine model, mice without iNKT cells had less T cell response and less dengue disease severity [46]. However, whether iNKT cell activation leads to T cells activation in human DV infection is not known and require further study. The possible crosstalk of iNKT cells with other immune cells such as B cells and NK cells in DV infection are also subjects of interest for future study.

Secondary dengue infection is associated with higher disease severity. It would be interesting to compare iNKT cell response in primary and secondary dengue infection. However, because Thailand is a hyper endemic area, most of our cohort samples are secondary DV infection. Therefore, primary infection was not evaluated in this current study.

In summary, we provide the first evidence that iNKT cells may play a role in human DV infection, one of the most important and expanding global health problems. As neither vaccine nor specific treatment are available for DV infection, and detrimental immune response might cause severe disease rather than protect the host, a better understanding of how immune response are regulated is crucial. We showed here the possible involvement of iNKT cells in human DV infection. Therefore, CD1d and iNKT cells may serve as attractive targets for designing novel strategy to help alleviate suffering from DV infection in the future.

Supporting Information

Figure S1 The percentage and absolute number of peripheral blood iNKT cells during the course of dengue infection. a, b) The percentage of iNKT cells during the course of dengue infection in each patient with DF (a) and DHF (b). Each line connects data from each patient at different time points. c, d) Each dot represents the absolute numbers of iNKT cells (x10³ cells/ml) of each patient in DF (c) and DHF (d) groups at 3 different time points, each line represents median of each group. e) The absolute number of iNKT cells during day -1 of OFI, DF

PLOS Neglected Tropical Diseases | www.plosntds.org 9 June 2014 | Volume 8 | Issue 6 | e2955
and DHF. f, g] The absolute iNKT cells during the course of dengue infection in DF (f) and DHF (g) groups. Each line connects data from each patient at different time points. Mann-Whitney test (c-e), and Wilcoxon signed rank test (a-b, f-g) were used for statistical comparison, *p < 0.05, **p < 0.010, ***p < 0.0010. (TIF)

**Figure S2 Contour plot of cytokines production by iNKT cells at day 0 and month 6.** Pregated on iNKT cells, representative contour plots show the production of IFN-γ (a) or IL-4 (b) within iNKT cells in comparison to isotype control in healthy, OFI, DF and DHF groups, at day 0 or 6 months, with (stimulated) and without (unstimulated) α-GalCer stimulation. (TIF)

**Figure S3 Contour plot of cytokines production by iNKT cells at day -1 and week 2.** Pregated on iNKT cells, representative contour plots show the production of IFN-γ (a) or IL-4 (b) within iNKT cells in comparison to isotype control in healthy, OFI, DF and DHF groups, at day 0 or 6 months, with (stimulated) and without (unstimulated) α-GalCer stimulation. (TIF)

**Figure S4 Cytokines production by iNKT cells from dengue infected patients at day -1 and week2 with and without stimulation with α-GalCer.** Each dot represents percentage of interferon gamma (IFN-γ)**+** (a-b) and IL-4**+** (c-d) iNKT cells from DF (a,c) and DHF (b,d) at day -1 and week 2, with (stimulated) and without (unstimulated) α-GalCer stimulation. At day -1 (c, g, i) and week 2 (d, h, j), percentage of IFN-γ**+** iNKT cells (c,d), IL-4**+** iNKT cells (g, h) and IFN-γ/IL-4 ratio (i, j) upon α-GalCer stimulation, comparing cells from healthy, OFI, DF and DHF groups. Mann-Whitney test, were used for statistical comparison, *p < 0.05 was considered as statistically significant difference (*p < 0.05). (TIF)

**Figure S5 CD1d expression on monocytes correlates with the activation of iNKT cells.** Spearman rho’s correlation analysis of %CD69**+** iNKT cells and difference in mean fluorescence intensity (dMFI) of CD1d on monocytes in all patients combined (a) or in only patients with dengue hemorrhagic fever (DHF) (b).

**Table S1 Characteristics of the patients (samples used for phenotypic analysis of peripheral blood iNKT cells).** (PDF)

**Table S2 Characteristics of the patients (samples were used for ex vivo functional analysis of peripheral blood iNKT cells).** (PDF)

**Acknowledgements**

We are grateful to all participants of this study. We thank Drs. S. Sirisingha and O. Matangkasombut for critically reviewing this manuscript. We also appreciate N. Techasan, A. Songjaeng, K. Jaisuk for technical assistance, K. Manopwisedjaroen for performing DV qRT-PCR, Dr. P. Suriyaphol for clinical data management, nursing team for samples and clinical data collection, the United States NIH tetramer facility for CD1d tetramer and flow cytometry facility, Faculty of Medicine, Siriraj Hospital, and central instrument facility, Faculty of Science, Mahidol University for instruments support.

**Author Contributions**

Conceived and designed the experiments: PM JM. Performed the experiments: PM WC. Analyzed the data: PM WC AO TD JM. Contributed reagents/materials/analysis tools: NT SV WL PM TD GS JM. Wrote the paper: PM WC.
