The temporal Talbot effect refers to the periodic revivals of a pulse train propagating in a dispersive medium, and is a temporal analog of the spatial Talbot effect with group-velocity dispersion in time replacing diffraction in space. Because of typically large temporal Talbot lengths, this effect has been observed to date in only single-mode fibers, rather than with freely propagating fields in bulk dispersive media. Here we demonstrate for the first time the temporal Talbot effect in free space by employing dispersive space-time wave packets, whose spatio-temporal structure induces group-velocity dispersion of controllable magnitude and sign in free space.

The Talbot effect, reported for the first time in 1836 [1], refers to the axial revivals of an initially periodic transverse field structure [2]. This fascinating phenomenon has found a broad range of applications, spanning structured illumination in fluorescence microscopy [3–5] to prime-number decomposition [6], and phase-locking of laser arrays [7]. In an analogous temporal Talbot effect, whereupon group velocity dispersion (GVD) in time replaces diffraction in space [8–9], a periodic pulse train of period $T$ traveling in a dispersive medium undergoes periodic revivals at multiples of the temporal Talbot distance $z_T = \frac{T^2}{2k_2^2}$, where $k_2$ is the GVD parameter [9]. This effect was proposed in [10], demonstrated experimentally in [11] (and subsequently in [12–13]), and has been exploited in removing pulse distortion [14] and in pulse-rate multiplication [12–15].

The temporal Talbot effect has yet to be observed in a freely propagating optical field. Because dispersion lengths for typical pulse trains is usually very large, the temporal Talbot effect has been instead realized only in single-mode fibers ($z_T$ on the order of kilometers, with $k_2 \approx -26$ fs$^2$/mm at 1500 nm) [11], or in fiber Bragg gratings with higher GVD [13] ($z_T$ on the order of tens of centimeters with $k_2 \approx -10^9$ fs$^2$/mm) [Fig. 1(a)], but not in dispersive bulk media where diffraction that unavoidably accompanies propagation hampers its observation.

Here we demonstrate – for the first time to the best of our knowledge – the temporal Talbot effect in a freely propagating field over short distances (a few centimeters) in free space, without resort to any dispersive medium [Fig. 1(b)]. This surprising effect is made possible by exploiting dispersive ‘space-time’ (ST) wave packets [16]. In general, ST wave packets [17–19] are pulsed beams endowed with a precise spatio-temporal structure [20–22] inculcating angular dispersion [23–24], by virtue of which they display a variety of unique behaviors, including propagation invariance [25–30], tunable group velocities in absence of dispersion [31–33], self-healing [34], free-space acceleration/deceleration [35–38]; among many other possibilities [39–42]. Rather than propagation-invariant ST wave packets, observing the temporal Talbot effect requires utilizing their counterparts exhibiting GVD in free space [16]. Because the angular dispersion underpinning ST wave packets is non-differentiable [43], unlike conventional angular dispersion associated with tilted pulse fronts (TPFs) that is differentiable [23–24], ST wave packets can experience arbitrary GVD in free space [16], whereas TPFs can experience only anomalous GVD [23–24] [44]. After introducing normal or anomalous GVD of large magnitude, periodically sampling the temporal spectrum of the ST wave packet produces the temporal Talbot effect with $z_T$ on the order of a few centimeters ($\approx 2$ cm here). Crucially, because the spatial and temporal degrees of freedom are coupled,
the initial (non-periodic) spatial profile is repeated at the temporal Talbot planes, thereby facilitating unambiguous observation of on-axis temporal revivals in free space for the first time.

We start by describing propagation-invariant ST wave packets in which each spatial frequency $k_x$ is associated with a single temporal frequency $\omega$ to ensure that the axial wave number $k_z$ is related linearly to $\omega$, $\Omega = (k_z - k_o)c\tan\theta$; here $\Omega = \omega - \omega_o$ is the temporal frequency relative to a fixed frequency $\omega_o$, $k_o = \frac{\pi}{2}$ is the corresponding wave number, $c$ is the speed of light in vacuum, $x$ and $z$ are the transverse and longitudinal coordinates, respectively, the field is held uniform along $y$ for simplicity, and we refer to $\theta$ as the spectral tilt angle. Geometrically, this construction is equivalent to restricting the spatio-temporal spectrum on the surface of the light-cone $k_x^2 + k_z^2 = (\frac{\omega}{c})^2$ to its intersection with a plane that is parallel to the $k_x$-axis and is tilted by an angle $\theta$ with respect to the $k_z$-axis, such that its projection onto the $(k_x, \frac{\omega}{c})$-plane is the straight line $k_x = k_o + \frac{\Omega}{c}\cot\theta$. Such a ST wave packet is propagation-invariant $\psi(x,z;t) = \psi(x,0;t - z/\bar{v})$, where $\psi(x,z;t)$ is the spatio-temporal envelope of the field $E(x,z,t) = e^{i(k_xz - \omega t)}\psi(x,z,t)$, and $\bar{v} = c\tan\theta$ is the group velocity [25]. By replacing the plane with a planar curved surface that is also parallel to the $k_x$-axis but whose projection onto the $(k_x, \frac{\omega}{c})$-plane is the curve $k_z = k_o + \Omega/\bar{v} + k_o^2\Omega^2/2$, the envelope takes the form:

$$\psi(x,z;t) = \int d\Omega\bar{\psi}(\Omega)e^{ik_x(x/t)}e^{-i\Omega(t-z/\bar{v})}e^{i\frac{\Omega^2}{2}\frac{\omega}{c}}. \tag{1}$$

The on-axis envelope $\psi(0,z;t)$ takes the form of a plane-wave pulse undergoing GVD (with GVD parameter $k_2$) along $z$, albeit in absence of a dispersive medium.

We introduce a periodic pulse train structure into the field by discretizing the temporal spectrum along $\omega$ at multiples of $\frac{\Omega}{2^m}, \Omega \rightarrow \Omega_m = m\frac{\Omega}{2^m}$ for integer $m$, so that the on-axis envelope is:

$$\psi(0,z;t) = \sum_m \bar{\psi}_m e^{-i2\pi m(t-z/\bar{v})/T}e^{i2\pi \text{sgn}(k_2) m^2 z/\tau_z}, \tag{2}$$

where $\text{sgn}(k_2) = \pm 1$ is the sign of $k_2$, $\bar{\psi}_m = \bar{\psi}(\Omega_m)$ and $\tau_z = T^2/\pi|k_2|$. The tight association between temporal and spatial frequencies entails simultaneously discretizing the spatial spectrum along $k_x$. However, because $\omega$ and $k_x$ are not linearly related, $k_x$ is therefore not sampled periodically, and the transverse spatial profile at $z = 0$ is thus not periodic. It is clear that the initial envelope is periodic in time $\psi(0,0;t) = \psi(0,0; t)$, and undergoes axial revivals at the Talbot planes $\psi(0,\ell_T t; t) = \psi(0,0; t - \ell z/\bar{v})$ in a time frame traveling at $\bar{v}$.

We prepare the ST field using the 2D pulse synthesizer developed in Refs. [25, 31-33] and shown schematically in Fig. 1(b). This arrangement implements a two-step spatio-temporal spectral synthesis strategy capable of producing arbitrary, non-differentiable angular dispersion [10, 45, 46]. Plane-wave pulses (pulsedwidth $\approx 100$ fs at a central wavelength $\approx 800$ nm) from a mode-locked Ti:sapphire laser (Tsunami; Spectra Physics) are directed to a diffraction grating that spreads the pulse spectrum in space, whereupon the first diffraction order is collimated with a cylindrical lens before impinging on a reflective, phase-only spatial light modulator (SLM). The SLM imparts a 2D phase distribution to the spectrally resolved wave front that assigns to each wavelength $\lambda$ a spatial frequency $k_z(\lambda)$ to guarantee that $k_z(\Omega, \lambda) = k_o + \Omega/\bar{v} + k_o^2\Omega^2/2$, for given $\bar{v}$ and $k_o$. The retro-reflected field returns to the grating whereupon the ST wave packets are reconstituted with an on-axis pulsedwidth of $\approx 2$ ps. We measure the spatio-temporal spectrum via a combination of a grating and a lens to carry out temporal and spatial Fourier transforms, and we obtain the spatio-temporal intensity profile by inter-
FIG. 3. Demonstration of the temporal Talbot effect in free space employing the dispersive ST wave packet experiencing normal dispersion in free space from Fig. 2(b).

We plot in Fig. 2 the measured spatio-temporal spectra for dispersive ST wave packets. In Fig. 2(a) we plot the spectral projections onto the \((k_x, \lambda)\) and \((k_z, \lambda)\) planes for normal GVD whereupon the spectral projection onto the \((k_x, \lambda)\)-plane is O-shaped. The GVD parameter here is \(k_2 = 10^6 \text{ fs}^2/\text{mm}\), which is significantly larger than ZnSe \(k_2 \approx 10^3 \text{ fs}^2/\text{mm}\) (at \(\lambda = 800 \text{ nm}\)) and Bragg gratings \((k_2 \approx 10^5 \text{ fs}^2/\text{mm})\). Once the temporal spectrum is discretized [Fig. 2(b)] to produce a period \(T = 8 \text{ ps}\), an on-axis \((x = 0)\) periodic pulse-train structure emerges with a predicted temporal Talbot length of \(z_T \approx 20 \text{ mm}\) because of the rapidly dispersing wave packet. We plot in Fig. 2(c) the measured spatio-temporal spectral projections onto the \((k_x, \lambda)\) and \((k_z, \lambda)\) planes after introducing anomalous GVD equal in magnitude but opposite in sign to that in Fig. 2(a). In absence of GVD, the projection onto the \((k_x, \lambda)\) is a parabola, but becomes V-shaped in presence of large anomalous GVD. We then plot in Fig. 2(d) the spectral projections and intensity profiles after spectral discretization with \(T = 8 \text{ ps}\).

Despite the clear distinction between the profiles for normally dispersive ST fields with continuous and discretized spectra [Fig. 2(a,b)] and their anomalously dispersive counterparts [Fig. 2(c,d)], the on-axis intensity in both are nevertheless similar (Eq. 1) with both exhibiting axial revivals of the initial periodic temporal profile. The measurement results for axial propagation of the dispersive ST wave packets alongside theoretical predictions are presented in Fig. 3 for normal GVD corresponding to Fig. 2(b), and in Fig. 4 for anomalous GVD corresponding to Fig. 2(d), both with \(T = 8 \text{ ps}\). We measure the temporally resolved intensity at the axial planes \(z = 0, 0.5z_T, 0.625z_T, 0.75z_T, 0.875z_T, z_T\), and \(1.5z_T\). There is excellent agreement between the calculated (first column) and measured (second column) intensity profiles. The on-axis temporal profiles (third column) reveal several critical features. First, the initial period profile [Fig. 3(a) and Fig. 4(a)] is retrieved at the Talbot planes \(z = mz_T\) [Fig. 3(f) and Fig. 4(f)]. Second, the periodic profile is reconstructed at the Talbot half-planes \(z = (m + \frac{1}{2})z_T\) but with a temporal displacement by \(T/2\) with respect to \(z = mz_T\) [Fig. 3(c) and Fig. 4(c)]. Third, at \(z = 0.25z_T\) a rate doubling is observed; i.e., a periodic profile is observed but with period \(T/2\) rather than \(T\) [Fig. 3(c) and
FIG. 5. (a) Measured temporal Talbot length $z_T$ while varying the GVD parameter in the normal regime. The dotted curve is $z_T = T^2/\pi |k_2|$. (b) The time-averaged intensity $I(x, z)$ for both normal and anomalous GVD, showing axial invariance despite the underlying temporal evolution (Fig. 3 and Fig. 4).

We recently reported a phenomenon we denoted the ‘veiled’ Talbot effect resulting from periodically sampling the spatial spectrum along $k_x$ for a propagation-invariant ST wave packet [47]. The conventional spatial Talbot effect was observed in time-resolved measurements as a consequence of time diffraction [26, 48–50], but no temporal dynamics are observed in absence of GVD. The time-averaged intensity (or energy) is diffraction-free along $z$ with a period $L/2$ rather than $L$. In the work reported here, the transverse profile is not periodic, and yet the time-averaged intensity remains diffraction-free, as shown in the measurements plotted in Fig. 5(b) for normal and anomalous GVD, despite the underlying axial dynamics (Fig. 3 and Fig. 4).

We have also reported on a ST Talbot effect based on the unique dispersive ST wave packet denoted a ‘V-wave’ whose diffraction and dispersion lengths are intrinsically equal [51]. Because $k_x$ and $\omega$ are linearly related in a V-wave, $k_x$ and $\omega$ can be simultaneously sampled periodically to guarantee equal spatial and temporal Talbot lengths. However, this is a restrictive condition that admits of this unique solution. The Talbot effect we present here is purely temporal, and a broad range of dispersive ST wave packets can be utilized in realizing it. Crucially, V-waves are endowed with differentiable angular dispersion, so they are amenable to the conventional perturbative theory [44] and they therefore can inculcate only anomalous GVD. In contrast, non-differentiable angular dispersion is introduced in the the dispersive ST fields examined here [43] and they can undergo either normal or anomalous GVD [16].

In conclusion, we have observed for the first time the temporal Talbot effect with a freely propagating field rather than a confined mode in a single-mode fiber. This demonstration made use of dispersive ST wave packets undergirded by non-differentiable angular dispersion that allows us to induce in free space normal or anomalous GVD of extremely large magnitudes, thus reducing the temporal Talbot length to $z_T \sim 20$ mm. Moreover, the initial non-periodic spatial profile is simultaneously revived at the temporal Talbot planes, thereby allowing for the unambiguous observation of this effect.
