(Dated: May 10, 2014)

We discuss the possibility of using experiments timing the propagation of neutrino beams over large distances to help determine the absolute masses of the three neutrinos.

PACS numbers: 14.60 Pq

I. INTRODUCTION

Determining the absolute values of the three neutrino masses is a subject of great interest. Historically, Pauli introduced the concept of the neutrino in order to explain why the energy of the emitted electron in beta decay did not have a single value as expected for a two body final state, but had a spectrum of energies (for different observations of the process). Fermi then suggested experimentally determining the mass of the neutrino by precisely measuring the electron’s energy spectrum in the endpoint region. This procedure has yielded steadily decreasing upper bounds on neutrino mass for more than half a century. It has however turned out to be difficult to reach the range suggested by the cosmology bound \cite{1} for the three different neutrinos now known to exist:

\[(m_1 + m_2 + m_3)c^2 \leq 0.3eV\] \hfill (1)

This bound is based on the gravitational force exerted by neutrinos in the universe rather than directly from neutrino kinematics. However, heroic efforts \cite{2} - \cite{7} are continuing to make steady progress on finding the neutrino masses using the kinematics of the tritium beta decay reaction.

One of course has the associated problem of finding the masses of all three neutrino mass eigenstates. The neutrino oscillation experiments \cite{8} - \cite{15} have determined these mass differences up to an ambiguity of either a “normal” or an “inverse” hierarchy. Specifically,

\[A = (m_2)^2 - (m_1)^2 = (7.59 \pm 0.21) \times 10^{-5} eV^2,\]
\[C = |(m_3)^2 - (m_1)^2| = (2.50 \pm 0.13) \times 10^{-3} eV^2,\] \hfill (2)

where the numbers have been taken from the recent review \cite{16}. Of course, the two hierarchies correspond to the two possible signs of \((m_3)^2 - (m_1)^2\). Evidently, measuring any combination of three neutrino masses which is independent of \(A\) and \(C\) should determine, for each hierarchy choice, the values of all three neutrino masses.

II. TOWARD FINDING THE ABSOLUTE NEUTRINO MASSES

Here we would like to discuss some aspects related to the possibility of finding the separate (or “absolute”) neutrino masses with the help of experiments measuring neutrino velocities by timing laboratory-made neutrino beams traveling from one point to another. At the moment, and for the near future, these are “thought experiments”. However, thinking about them, raises a number of interesting questions.

If there were just a single neutrino it is clear that we could “trivially” find its mass, \(m\) by measuring its velocity, \(v\) as well as its energy, \(E\) and using Einstein’s formula:

\[E = \frac{m}{\sqrt{1-v^2}} \approx \frac{m}{\sqrt{2}c},\] \hfill (3)
where we are working in units where the velocity of light, $c = 1$ and $v = 1 - c$, appropriate to neutrinos traveling just slightly less than the speed of light.

For definiteness, in the realistic 3-neutrino world, we assume a neutrino beam initiated in association with muons and detected, after traveling a measured time and distance, by produced muons. We designate this as a mu-neutrino type beam. Now we must take account of the fact that the laboratory neutrino beam in this setup corresponds to working with a neutrino “flavor” eigenstate (of muonic type) rather than a mass eigenstate. A prescription is therefore required to define what might be called the “averaged neutrino mass” $m$ which enters into Eq. (3) when we want to use it in the 3-flavor world. In Quantum Mechanics the mu-type neutrino corresponds to a linear combination of the three mass eigenstates:

$$\nu_{\mu} = K_{21}\nu_1 + K_{22}\nu_2 + K_{23}\nu_3, \quad (4)$$

where the $K_{2i}$’s are approximately the elements of the leptonic mixing matrix. In models, say for the case of Majorana neutrinos, the mixing results from bringing an “original” mass matrix $M$ to diagonal form $M_{\text{diag}}$.

$$M_{\text{diag}} = K^T M K, \quad (5)$$

where $K$ is unitary. The “to-be-measured” mass, $m$ will thus be interpreted [17] as the “averaged” quantity,

$$m = M_{22} = (K_{2i})^2 m_i, \quad (6)$$

where the repeated index, $i$ should be summed over. We also have assumed for simplicity that the $K_{ii}$’s are real. As a check of this formula, one notes that if the neutrinos didn’t mix we would have $K_{2i} = \delta_{2i}$ and $m = m_2$.

Present experimental information on the “angles” which parameterize the matrix $K$ are summarized in ref. [18]. Translating these angles to the needed matrix elements, $K_{2i}$ yields the numerical values with estimated errors:

$$K_{21} = 0.21 \pm 0.05$$
$$K_{22} = 0.68 \pm 0.05$$
$$K_{23} = 0.70 \pm 0.05 \quad (7)$$

Eq. (6) then explicitly gives the to-be-measured quantity, $m$ as a different combination of the masses than those in Eq. (2). Thus combining the three equations we can find the absolute neutrino masses for each hierarchy choice. For example, we may eliminate $m_2$ and $m_3$ in terms of $m_1$ by using Eqs. (2) to get

$$m = (K_{21})^2 m_1 + (K_{22})^2 \sqrt{A + (m_1)^2} + (K_{23})^2 \sqrt{B + (m_1)^2}. \quad (8)$$

Here the plus sign corresponds to the normal hierarchy choice and the minus sign corresponds to the inverted hierarchy choice. For the normal hierarchy we can, using this equation, obtain the curve in Fig 1 while for the inverted hierarchy we obtain the curve in Fig. 2.

Thus if an average mass, $m$ is measured by a long baseline time of flight experiment, we can read $m_1$ from this curve and find also (from the known differences above), both $m_2$ and $m_3$. This should be done for both hierarchy assumptions; the present method does not determine which hierarchy is the one nature chooses.

Of course, there are some important experimental errors introduced in this determination. It is expected that further experimental measurements of neutrino oscillations will substantially improve the experimental accuracy.

This procedure thus appears to be able to reasonably solve the problem of relating the “averaged” mass, $m$ measured by using Eq. (6) to the three neutrino mass eigenvalues $m_i$. However, we are not done since we should pay some attention to the accuracy to which $m$ itself can be determined.

It should be remarked that the need to take mixtures of mass eigenstates into account is also evident in the electron endpoint of beta decay method for absolute neutrino mass determination. In that case the $K_{ii}$’s appear instead of the $K_{2i}$’s; see for example Eq. (21) of [19].

Next, we discuss the needed determination of the averaged mass, $m$ by a long baseline time of flight measurement. First the mu-neutrino, $\nu_{\mu}$ must be produced. We would like to select the $\nu_{\mu}$ to have as small an energy as possible in order that it travel at as low a speed, $v$ as possible.

An at least conceptually convenient source in this context might use the decay process:
FIG. 1: Plot of $m$ versus $m_1$ for normal hierarchy. The solid line corresponds to the mass $m$ “measured” in a time of flight experiment. The two dotted lines give the error estimates for the corresponding $m_1$.

FIG. 2: Plot of $m$ versus $m_1$ for inverted hierarchy. The solid line corresponds to the mass $m$ “measured” in a time of flight experiment. The two dotted lines give the error estimates for the corresponding $m_1$.

$K^+ \rightarrow \mu^+ + \nu_{\mu}$. \hspace{1cm} (9)

By selecting the $K^+$ and $\mu^+$ momenta one can reduce the energy of the $\nu_{\mu}$ and hence its speed, $v$. That would make a precise time measurement easier. From Eq. (3), the deviation of the neutrino’s speed from that of light is given by:

$$\epsilon = 1 - v = \frac{1}{2} \left( \frac{m}{E} \right)^2.$$ \hspace{1cm} (10)

If one were to select the neutrino energy to be 1 MeV, this would result in $\epsilon$ to be of the order of $10^{-14}$. That corresponds to a deviation from the velocity of light in the fourteenth decimal place, which does not seem practical. However, if one were able to get enough data with a neutrino energy selected to be 1 KeV, $\epsilon$ would be of the order of $10^{-8}$ which should be measurable.

III. SUMMARY

We have shown how measurements of, for example, a mu-neutrino beam velocity and energy can be used to help in the determination of the absolute masses of the presently known three neutrinos. This could be a supplement to the determinations obtained using the endpoint of tritium beta decay method.
Of course, an important question is the accuracy which can be achieved. In addition to the accuracy of the velocity and energy measurements of the beam it is important to increase the accuracy of the neutrino mass differences and the lepton mixing matrix elements obtained via neutrino oscillation experiments. A recent review of these is given in [18].

Acknowledgments
