Introduction. Neutron-proton pairing correlations play an important role in a number of contexts [1, 2], including the study of medium mass $N \approx Z$ nuclei produced at the radioactive nuclear beam facilities [3] and the process of deuteron formation in medium-energy heavy ion collisions [4]. For not too low densities, $np$ pairing correlations crucially depend on the overlap between neutron and proton Fermi surfaces and even small isospin asymmetry effectively destroys a condensate with $np$ Cooper pairs due to the Pauli blocking effect [3, 4, 5]. However, under decreasing density, when neutrons and protons start to bind in deuterons and the spatial separation between deuterons, and between deuterons and extra neutrons is large, the Pauli blocking loses its efficiency in destroying a $np$ condensate. In such a situation, despite the fact that the isospin asymmetry may be very large, a $np$ condensate survives and exists in the form of a Bose-Einstein condensate of deuterons.

The transition from BCS superconductivity to Bose–Einstein condensation (BEC) occurs in a Fermi system, if either density is decreased or the attractive interaction between fermions is increased sufficiently. This transition was studied, first, in superconducting semiconductors [3] and then in an attractive Fermi gas [4]. Later it was realized that an analogous phase transition takes place in symmetric nuclear matter, when $np$ Cooper pairs at higher densities go over to Bose–Einstein condensate of deuterons at lower densities [4, 5]. During this transition the chemical potential changes its sign at certain critical density (Mott transition), approaching half of the condensation between deuterons, and between deuterons and protons start to bind in deuterons and the spatial separation between deuterons, and between deuterons and extra neutrons is large, the Pauli blocking loses its efficiency in destroying a $np$ condensate. In such a situation, despite the fact that the isospin asymmetry may be very large, a $np$ condensate survives and exists in the form of a Bose-Einstein condensate of deuterons.

The density, spin and isospin correlation functions in nuclear matter with a neutron-proton ($np$) condensate are calculated to study the possible signatures of the BEC-BCS crossover in the low-density region. It is shown that the criterion of the crossover (Phys. Rev. Lett. 95, 090402 (2005)), consisting in the change of the sign of the density correlation function at low momentum transfer, fails to describe correctly the density-driven BEC-BCS transition at finite isospin asymmetry or finite temperature. As an unambiguous signature of the BEC-BCS transition, there can be used the presence (BCS regime) or absence (BEC regime) of the singularity in the momentum distribution of the quasiparticle density of states.

Two-body correlation functions in nuclear matter with $np$ condensate

The recent upsurge of interest to the BEC-BCS crossover is caused by finding the BCS pairing in ultracold trapped quantum atom gases [13, 14]. In this study we examine the possible signatures of the BEC-BCS crossover in low-density nuclear matter. It may have interesting consequences, for example, in the far tails of the density profiles of exotic nuclei, where a deuteron condensate can exist in spite of the fact that the density there can be quite asymmetric. Besides, similar physical effects can play an important role in expanding nuclear matter, formed in heavy ion collisions, or in nuclear matter in the crust of a neutron star. The main emphasis is laid on the behavior of the density, spin and isospin correlation functions across the BEC-BCS transition region. The study is motivated by the results of Ref. [15], where the authors state that the density correlation function of a two-component ultracold fermionic gas of atoms changes sign at low momentum transfer and this represents an unambiguous signature of the BEC-BCS crossover. This statement is checked for nuclear matter taking into account additional factors: finite isospin asymmetry or finite temperature. In both cases, this criterion fails to provide a correct description of the density-driven BEC-BCS crossover and cannot serve as the universal feature of transition between two states of the system.

Basic equations. Superfluid states of nuclear matter are described by the normal $f$ and anomalous $g$ distribution functions of nucleons

$$f_{\kappa 1\kappa 2} = \text{Tr} \varphi a^\dagger_{\kappa 2} a_{\kappa 1}, \quad g_{\kappa 1\kappa 2} = \text{Tr} \varphi a_{\kappa 2} a_{\kappa 1},$$

where $\kappa \equiv (k, \sigma, \tau)$, $k$ is momentum, $\sigma(\tau)$ is the projec-
Introducing the anomalous density fluid with singlet spin pairing between unlike fermions. We shall study $np$ pairing correlations in the pairing channel with total spin $S$ and isospin $T$ of a pair $S = 1, T = 0$ and the projections $S_z = T_z = 0$. In this case the distribution functions for isospin asymmetric nuclear matter have the structure

$$f(k) = f_{00}(k)\sigma_0\tau_3 + f_{01}(k)\sigma_0\tau_2,$$

$$g(k) = g_{30}(k)\sigma_3\sigma_2\tau_2,$$

where $\sigma_i$ and $\tau_3$ are the Pauli matrices in spin and isospin spaces, respectively. Using the minimum principle of the thermodynamic potential and procedure of block diagonalization, one can obtain expressions for the distribution functions

$$f_{00}(k) = \frac{1}{2} - \frac{\xi_k}{4E_k} \left( \tanh \frac{E^+_k}{2T} + \tanh \frac{E^-_k}{2T} \right),$$

$$f_{01}(k) = \frac{1}{4} \left( \tanh \frac{E^+_k}{2T} - \tanh \frac{E^-_k}{2T} \right),$$

$$g_{30}(k) = -\frac{\Delta(k)}{4E_k} \left( \tanh \frac{E^+_k}{2T} + \tanh \frac{E^-_k}{2T} \right).$$

Here

$$E_k^\pm = E_k \pm \delta \mu = \sqrt{\frac{\xi_k^2}{4} + \Delta(k)} \pm \delta \mu,$$

$\xi_k = \frac{k^2}{2m} - \mu$, (6)

$\Delta$ being the energy gap in the quasiparticle excitation spectrum, $m$ being the effective nucleon mass, $\mu$ and $\delta \mu$ being half of a sum and half of a difference of neutron and proton chemical potentials, respectively.

Equations, governing $np$ pairing correlations in the $S = 1, T = 0$ pairing channel, can be obtained on the base of Green’s function formalism and have the form [4, 7, 11]

$$\Delta(k) = -\frac{1}{V} \sum_{k'} V(k, k') \frac{\Delta(k')}{2E_{k'}} (1 - f(E^+_{k'}) - f(E^-_{k'})),$$

$$\varrho = \frac{2}{V} \sum_k \left( 1 - \frac{\xi_k}{E_k} [1 - f(E^+_k) - f(E^-_k)] \right) = \frac{2}{V} \sum_k n_k,$$

$$\alpha \varrho = \frac{2}{V} \sum_k \left( f(E^+_k) - f(E^-_k) \right),$$

and using Eq. (3), one can represent Eq. (7) for the energy gap in the form

$$\frac{k^2}{m} \psi(k) + (1 - n_k) \sum_{k'} V(k, k') \psi(k') = 2\mu \psi(k).$$

In the limit of vanishing density, $n_k \to 0$, Eq. (10) goes over into the Schrödinger equation for the deuteron bound state [4, 10, 11]. The corresponding energy eigenvalue is equal to $2\mu$. The change in the sign of the mean chemical potential $\mu$ of neutrons and protons under decreasing density of nuclear matter signals the transition from the regime of large overlapping $np$ Cooper pairs to the regime of non-overlapping bound states (deuterons).

Let us consider the two-body density correlation function

$$D(x, x') = \text{Tr}_g \Delta \hat{n}(x) \Delta \hat{n}(x'), \quad \Delta \hat{n}(x) = \hat{n}(x) - \hat{n},$$

$$\hat{n}(x) = \sum_{\sigma \tau} \psi_\sigma^+ (x) \psi_\sigma (x) = \frac{1}{V} \sum_{\sigma \tau \mathbf{k} \mathbf{k}'} e^{i(k' - k)x} a_{\mathbf{k}\sigma}^+ a_{\mathbf{k}'\sigma},$$

$$\hat{n} = \frac{1}{V} \sum_{\sigma \tau \mathbf{k}} a_{\mathbf{k}\sigma}^+ a_{\mathbf{k}\sigma}.$$

Its general structure in the spatially uniform and isotropic case reads [10]

$$D(x, x') = g \delta(r) + g D(r), \quad r = x - x'$$

The function $D(r)$ is called the density correlation function as well. We will be just interested in the behavior of the function $D(r)$. The trace in Eq. (11) can be calculated, using definitions [11] and Wick rules. Taking into account Eqs. (2) and going to the Fourier representation

$$D(q) = \int d^3r e^{iqr} D(r),$$

one can get

$$D(q) = I_g^{30}(q) - I_f^{00}(q) - I_f^{03}(q),$$

where

$$I_g^{30}(q) = \frac{4}{\pi^2} \int_0^\infty dr r^2 j_0(rq) \left[ \int_0^\infty dk k^2 f_{00}(k) j_0(rk) \right]^2,$$

$$I_f^{30}(q) = \frac{4}{\pi^2} \int_0^\infty dr r^2 j_0(rq) \left[ \int_0^\infty dk k^2 f_{03}(k) j_0(rk) \right]^2,$$

$$I_g^{30}(q) = \frac{4}{\pi^2} \int_0^\infty dr r^2 j_0(rq) \left[ \int_0^\infty dk k^2 g_{30}(k) j_0(rk) \right]^2.$$

Here $j_0$ is the spherical Bessel function of the first kind and zeroth order. The functions $I_g^{30}, I_f^{30}$ and $I_g^{30}$ represent the normal and anomalous contributions to the density correlation function. Analogously, we can consider
the two-body spin correlation function
\[ S_{\mu \nu}(x, x') = \text{Tr} \delta \hat{s}_\mu(x) \Delta \hat{s}_\nu(x'), \quad \Delta \hat{s}_\mu(x) = \hat{s}_\mu(x) - \hat{s}_\mu, \]
\[ \hat{s}_\mu(x) = \frac{1}{2} \sum_{\sigma \sigma' \tau} \psi^+_\sigma(x) (\sigma_\mu)_{\sigma \sigma'} \psi_{\sigma' \tau}(x) \]
\[ = \frac{1}{2V} \sum_{\sigma \sigma' \tau \bar{k} k} e^{i(k' - k) \cdot x} a^{\dagger}_{\sigma \sigma' \tau k} (\sigma_\mu)_{\sigma \sigma'} a_{\sigma' \tau \bar{k}}, \]
\[ \hat{\delta}_\mu = \frac{1}{2V} \sum_{\sigma \tau' \bar{k} k} a^{\dagger}_{\sigma \tau' k} (\sigma_\mu)_{\sigma \sigma'} a_{\sigma \tau' \bar{k}}. \]
and the two-body isospin correlation function
\[ T_{\mu \nu}(x, x') = \text{Tr} \delta \hat{t}_\mu(x) \Delta \hat{t}_\nu(x'), \quad \Delta \hat{t}_\mu(x) = \hat{t}_\mu(x) - \hat{t}_\mu, \]
\[ \hat{t}_\mu(x) = \frac{1}{2} \sum_{\tau \tau' \bar{k} k} \psi^+_\tau(x) (\tau_\mu)_{\tau \tau'} \psi_{\tau' \bar{k} k}(x) \]
\[ = \frac{1}{2V} \sum_{\tau \tau' \bar{k} k} e^{i(k' - k) \cdot x} a^{\dagger}_{\tau \tau' k} (\tau_\mu)_{\tau \tau'} a_{\tau' \bar{k} k}, \]
\[ \hat{\delta}_\mu = \frac{1}{2V} \sum_{\tau \tau' \bar{k} k} a^{\dagger}_{\tau \tau' k} (\tau_\mu)_{\tau \tau'} a_{\tau \tau' \bar{k} k}. \]
Their general structure for isospin asymmetric nuclear matter without spin polarization is
\[ S_{\mu \nu}(x, x') = \frac{\rho}{4} \delta_{\mu \nu} \delta(r) + \rho S_{\mu \nu}(r), \] \[ T_{\mu \nu}(x, x') = \frac{\rho}{4} \delta_{\mu \nu} \delta(r) + \frac{\alpha \rho}{4} i \epsilon_{\mu \nu 3} \delta(r) + \rho T_{\mu \nu}(r). \]
Then, calculating traces in Eqs. (14), (15), for the Fourier transforms of the spin and isospin correlation functions one can get
\[ S_{\mu \nu}(q) = -\frac{\delta_{\mu \nu}}{4} \left( I^0_q + I^3_q \right) \] \[ + \frac{\alpha}{4} \left( \delta_{\mu \nu} - 2 \delta_{\mu \nu} \delta_{3 \nu} \right) I^{30}_q, \]
\[ T_{\mu \nu}(q) = -\frac{\delta_{\mu \nu}}{4} \left( I^0_q + I^3_q \right) \] \[ - \frac{\alpha}{4} \left( \delta_{\mu \nu} - 2 \delta_{\mu \nu} \delta_{3 \nu} \right) I^{30}_q. \]
Note that if to put \( \nu = \mu = 3 \) in Eqs. (18), (19), one gets the longitudinal spin \( S^l \) and isospin \( T^l \) correlation functions, while setting \( \mu, \nu = 1, 2 \) gives the transverse spin and isospin correlation functions
\[ S_{\mu \nu}^l(q) = -\frac{\delta_{\mu \nu}}{4} \left( I^0_q + I^3_q \right) \] \[ \equiv \delta_{\mu \nu} S^l(q), \]
\[ T_{\mu \nu}^l(q) = -\frac{\delta_{\mu \nu}}{4} \left( I^0_q - I^3_q \right) \] \[ \equiv \delta_{\mu \nu} T^l(q). \]
The following relationships between the correlation functions hold true
\[ S^{l}(q) = \frac{D(q)}{4}, \quad S^{l}(q) = T^{l}(q). \] At zero temperature and zero momentum transfer, the correlation functions satisfy the sum rule
\[ S^{l}(q = 0) = T^{l}(q = 0) \]
\[ = -\frac{1}{2\pi^2 \rho} \int dk k^2 \left( f^2_{00}(k) + f^2_{03}(k) + f^2_{30}(k) \right) = \frac{1}{4}, \]
where the r.h.s. is independent of density and isospin asymmetry. Besides, the transverse isospin correlation function satisfies the relationship
\[ T^{l}(q = 0) = -\frac{1}{2\pi^2 \rho} \int dk k^2 \left( f^2_{00}(k) - f^2_{03}(k) + g^2_{30}(k) \right) \]
\[ = -\frac{1 - \alpha}{4}, \]
where the r.h.s. is independent of density. **Correlation functions in nuclear matter with a np condensate.** Further for numerical calculations we shall use the effective zero range force, developed in Ref. 12 to reproduce the pairing gap in \( S = 1, T = 0 \) pairing channel with Paris NN potential:
\[ V(r_1, r_2) = v_0 \left( 1 - \frac{g (r_1 + r_2)}{\rho_0} \right)^\gamma \delta(r_1 - r_2), \]
where \( \rho_0 = 0.16 \text{ fm}^{-3} \) is the nuclear saturation density, \( v_0 = -530 \text{ MeV} \cdot \text{ fm}^3, \) \( \gamma = 0, m = m_G, m_C \) being the effective mass, corresponding to the Gogny force D1S. Besides, in the gap equation (7), Eq. (24) must be supplemented with a cut-off parameter, \( \varepsilon_c = 60 \text{ MeV}. \) Just this set of parameters, among total three parametrizations, used in Ref. 12, corresponds to the formation of bound states at nonzero energy in low-density region of nuclear matter.
To find the correlation functions one should first solve the gap equation (7) self-consistently with Eqs. (8), (9). Then the correlation functions can be determined directly from Eqs. (13), (15) and (17). The results of numerical determination of the energy gap as a function of density for different asymmetries at zero temperature are shown in Fig. 1. As one can see, with increasing asymmetry the magnitude of the energy gap is decreased and the density interval, where a np condensate exists, shrinks to lower density. In reality solutions exist for any \( \alpha < 1 \) (the phase curves for larger values of \( \alpha \) are not shown in Fig. 1) and correspond to the formation of BEC of deuterons at very low densities of nuclear matter.
Now we consider the correlation functions \( D(q) \) and \( S^l(q) \) for symmetric nuclear matter at zero temperature, depicted in Fig. 2 (at \( \alpha = 0, T^{l}(q) = S^{l}(q) \). The density correlation function changes sign at low momentum.
transfer when the system smoothly evolves from the BEC regime to the BCS one. These two regimes are distinguished by negative and positive values of the chemical potential $\mu$, respectively. In view of Eq. (21), the longitudinal spin correlation function $S^l(q)$ changes sign through the BEC-BCS crossover as well. The transverse spin correlation function, and, according to Eq. (21), the longitudinal and transverse isospin correlation functions change fluently between BEC and BCS limits. The behavior of the density correlation function in isospin symmetric case at zero temperature qualitatively agrees with the behavior of the density correlation function in an ultracold fermionic atom gas with singlet pairing of fermions [15]. In Ref. [15], the change in the sign of the density correlation function at low momentum transfer was considered as a signature of the BEC-BCS crossover. We would like to extend their calculations taking into account the finite isospin asymmetry and finite temperature.

Fig. 3 shows the dependence of the density correlation function $D(q = 0)$ at zero momentum transfer as a function of density for a set of various isospin asymmetry parameters and zero temperature. It is seen that with increasing the asymmetry parameter the density correlation function decreases. For strong enough asymmetry, the function $D(q = 0)$ is always negative. In accordance with the above criterion, the density region, where the function $D(q = 0)$ has positive or negative values, would correspond to the BEC or BCS regime, respectively. Hence, as follows from Fig. 3, for strong isospin asymmetry we would have only the BCS state for all densities where a $np$ condensate exists. Obviously, this conclusion contradicts with the behavior of the mean chemical potential $\mu$, being negative at very low densities for any $\alpha < 1$, and, hence, giving evidence to the formation of BEC of bound states [11]. Thus, at strong enough isospin asymmetry the criterion of the crossover, based on the change of the sign of the density correlation function, fails to predict the transition to the BEC of deuterons in low-density nuclear matter.

Now we consider symmetric nuclear matter at finite temperature. Fig. 4 shows the dependence of the density correlation function $D(q = 0)$ at zero momentum transfer as a function of density for a set of various temperatures. It is seen that for not too high temperatures the density response function is nonmonotonic and twice changes sign in the region of low densities. Hence, in accordance with the above criterion, we would have the density interval $\rho_1 < \rho < \rho_2$ with the BEC state, sur-
rounded by the density regions with the BCS state. However, this conclusion contradicts with the behavior of the mean chemical potential $\mu$ for these temperatures, being a monotone function of density and indicating the formation of a BEC state at low densities ($\mu < 0$) and a BCS state at larger densities ($\mu > 0$). Thus, at finite temperature the criterion of the crossover, formulated in Ref. [15], fails to provide the correct description of the transition between two regimes.

In summary, we have calculated the density, spin and isospin correlation functions in superfluid nuclear matter with $np$ pairing correlations, intending to find the possible signatures of the BEC-BCS crossover. It is shown that the transverse spin, and longitudinal and transverse isospin correlation functions satisfy the sum rule at zero momentum transfer and zero temperature, and change smoothly between BEC and BCS regimes. In Ref. [15], it was learned that the density correlation function in a two-component ultracold fermionic atom gas with singlet pairing of fermions changes sign at low momentum transfer across the BEC-BCS transition, driven by a change in the scattering length of the interaction at zero temperature. We have shown that for spin triplet pairing the longitudinal spin correlation function plays an analogous role to the density correlation function and changes sign at low momentum transfer across the crossover in symmetric nuclear matter at zero temperature. However, while giving a satisfactory description of the density-driven BEC-BCS crossover in dilute nuclear matter at zero temperature for the isospin symmetric case, this criterion fails to provide the correct description of the crossover at finite isospin asymmetry (nonequal densities of fermions of different species) or finite temperature. Hence, the criterion in Ref. [15] cannot be considered as the universal indication of the BEC-BCS transition. During the Mott transition, when the chemical potential changes sign, there is a qualitative change in the quasiparticle energy spectrum: the minimum shifts from a finite (BCS state) to zero-momentum value (BEC state) (see Eq. (6) and Ref. [17]). As such, the presence (BCS) or absence (BEC) of the singularity in the momentum distribution of the quasiparticle density of states represents the universal signature of the BEC-BCS transition. This transition may be relevant, and could give a valuable information on $np$ pairing correlations, in low-density nuclear systems, such as tails of nuclear density distributions in exotic nuclei, produced at radioactive nuclear beam facilities, expanding nuclear matter in heavy ion collisions, low-density nuclear matter in outer regions of neutron stars, etc.
