We present an experiment demonstrating high-resolution coherent control of a four-level atomic system in a closed (diamond) type configuration. A femtosecond frequency comb is used to establish phase coherence between a pair of two-photon transitions in cold $^{87}$Rb atoms. By controlling the spectral phase of the frequency comb we demonstrate the optical phase sensitive response of the diamond system. The high-resolution state selectivity of the comb is used to demonstrate the importance of the signs of dipole moment matrix elements in this type of closed-loop excitation. Finally, the pulse shape is optimized resulting in a 256% increase in the two-photon transition rate by forcing constructive interference between the mode pairs detuned from an intermediate resonance.

The field of coherent control of light-matter interactions for the purpose of driving a quantum system to a desired state has been drawing increasing interest. Research in the field of coherent control generally uses either an ultrashort pulse to create atomic coherences over a very large bandwidth, or in the other extreme, continuous wave (cw) lasers to drive transitions with high-resolution. Some of the pioneering work on coherent control used pulse shaping of a single broad-bandwidth pulse to enhance or diminish two-photon absorption [1, 2], improve the resolution of coherent anti-Stokes Raman scattering [3], and control molecular wavepacket motion [4]. Simultaneously, a tremendous amount of research has been done using narrow-bandwidth cw-lasers to control three-level atomic systems, for example to study electromagnetic induced transparency [5]. Particularly relevant to this Letter are the many theoretical studies of four-level systems, for example in a double-Lambda [6] or diamond type configuration [7, 8]. The advent of optical frequency combs has made a strong impact on the field of high-precision spectroscopy [9], and has recently been used for coherent control of a three-level transition [10].

In this work we combine the broad-bandwidth and high-resolution of the comb, augmented by discrete spectral phase shaping, to control the phase sensitive response of a four-level atomic system in a diamond configuration.

We use a femtosecond optical frequency comb to excite a pair of resonant two-photon transitions that form a closed diamond configuration in cold $^{87}$Rb. The broad-bandwidth of the femtosecond pulses allows for a two-photon transition to be excited via different intermediate states with a separation of 7 THz. Simultaneously the narrow linewidth of each comb mode allows the excitation of only specific atomic levels, a necessary condition to isolate the four-level diamond configuration from the full set of atomic transitions. The phase sensitive excitation of this closed four-level system is demonstrated by discrete spectral shaping of the femtosecond comb. The 7 THz separation between intermediate states allows use of a pulse shaper to change the phase of the comb mode that is resonant with one intermediate state and not the other resonant modes, this shifts the relative phase between the two paths constituting the diamond. By analogy with an optical interferometer, the two-photon excitation is shown to exhibit a sinusoidal variation versus the applied phase, due to the resonant comb modes alone. In the second experiment the off-resonant comb modes are of primary importance, in particular we show that the two-photon excitation is enhanced by changing the phase of the two-photon resonant mode pairs that are symmetrically detuned from an intermediate state.

The experiments presented in this Letter can be modeled as the interaction of a phase coherent train of shaped femtosecond pulses (an optical comb) with a four-level atomic system in a diamond configuration. A diamond configuration has one ground state, two intermediate states, and a single excited state such that there are a total of four possible resonant dipole allowed transitions. There are hundreds of thousands of frequency modes in the comb spectrum, four of which are tuned to be resonant with the transitions shown in Fig. 1(a). Due to the equidistant spacing of comb frequencies, any mode in the spectrum has another mode that forms a two-photon resonant pair. Therefore there are hundreds of thousands of mode pairs that are two-photon resonant but have varying detunings from the intermediate states, these will be referred to as off-resonant mode pairs. We present our experiments in two parts, the first focuses on the diamond configuration excited by resonant modes only, the second part utilizes another pulse shape to enhance the signal from the off-resonant mode pairs.

Two-photon absorption via a pair of modes and a single intermediate state gives rise to an excited state amplitude that within second-order perturbation is given by [11],

\[
c_{gf} \propto \frac{E_n E_m \mu_{gf} \mu_{if}}{i(\omega_{gf} - (m + n)2\pi f_r - 4\pi f_o) + \pi \gamma_f} \times \left[ \frac{1}{i(\omega_{gi} - 2\pi(n f_r + f_o) + \pi \gamma_i)} + \frac{1}{i(\omega_{gi} - 2\pi(m f_r + f_o) + \pi \gamma_i)} \right],
\]
where $E_{n,m}$ are the electric fields of the $n^{th}$ and $m^{th}$ modes of the comb, $\gamma_{i(f)}$ is the intermediate (final) state decay rate, $\omega_{\text{pi}}(gf)$ is ground to intermediate (final) state transition frequency, $f_r$ is the repetition frequency of the comb, $f_o$ is the comb offset frequency, and $\beta_{\text{pi}}(gf)$ are the dipole moments from the ground to intermediate (intermediate to final) states. The total excited state amplitude is then given by the sum of all the possible two-photon resonant transition pathways resulting from all comb mode pairs in the laser spectrum connecting through various intermediate states. The key physics for the results presented here is that the phase of the excited state amplitude is a function of the detuning from the intermediate state, the signs of dipole moment matrix elements, and the phase of the two electric fields. In particular, the phase of the excited state amplitude is a function of the detuning from the intermediate state, the signs of dipole moment matrix elements, and the phase of the two electric fields. The experiments are conducted on an ensemble of cold $^{87}$Rb atoms formed in a magneto-optical trap (MOT). It is necessary to use cold atoms to ensure that only the four intended atomic states are excited, in contrast to a Doppler broadened room temperature gas. A Kerr lens mode-locked Ti:Sapphire laser operating with an approximately 55 nm bandwidth centered at 778 nm with $f_r \approx 100$ MHz is used to excite all four transitions. $f_r$ is phase stabilized to a low phase-noise crystal oscillator, and steered via a Cesium reference to maintain the absolute frequency of the comb modes. The offset frequency $f_o$ is measured via a f-2f nonlinear interferometer and stabilized to a direct digital synthesizer. Regardless of the spectral phase of the pulses, any comb mode has an absolute frequency given by, $\nu_N = f_o + N \times f_r$, where $N$ is the mode order number (of order $10^6$ for our laser). Using prior knowledge of the $^{87}$Rb energy level structure for the 5S, 5P, and 5D hyperfine states, it is possible to select a particular $f_r$ and $f_o$ to approximate a diamond configuration with only four resonant levels (see Fig. 1(a)).

We use two values of $f_r$, the first is $f_r$=100.59660605 MHz with $f_o$=+16.94 MHz. In this case, the four resonant states are: 5S$_{1/2}$F=2, 5P$_{1/2}$F=2, 5P$_{3/2}$F=2, and 5D$_{3/2}$ F=1. With this selection of comb frequencies the transitions from 5S$_{1/2}$ F=1, the other ground state, are at least 6 MHz detuned from any intermediate and excited states. All other possible transitions are further detuned. Note that the 5S to 5P and 5D linewidths are 6 MHz and 0.66 MHz respectively. Using a slightly shifted $f_r$ of 100.59660525 MHz and the same $f_o$, the comb is resonant with the same intermediate and final states but from 5S$_{1/2}$ F=1. We indirectly measure the 5D population by counting photons from the 5D-6P-5S cascade fluorescence at 420 nm with a photomultiplier tube. The experimental cycle consists of three parts: first a MOT is formed for 6.5 ms, then the atoms are held in optical molasses for 3 ms while the magnetic field turns off, finally the atoms are excited for 0.5 ms and the photon counts are recorded versus time on a multichannel scaler. We use a standard 2f-2f configuration pulse shaper with a computer controlled spatial light modulator (SLM) to set the relative phase of the comb modes with a per pixel resolution of $\sim$150 GHz [13]. The spatial and temporal frequency chirp of the pulses at the MOT location are reduced to maximize the fringe visibility.

The first experiment provides a clear demonstration of the phase sensitive nonlinear response of the four-level

**FIG. 1:** (a) Energy level diagram of the diamond configuration in $^{87}$Rb, the arrows indicate the resonant comb modes. (b) Pulse spectrum and phase mask used for the first experiment. The hatched region in the spectrum and the inset energy level diagram indicates the portion of the spectrum to which the phase mask is applied. The four arrows indicate resonant wavelengths in relation to the phase mask spectral window.

The experiments are conducted on an ensemble of cold $^{87}$Rb atoms formed in a magneto-optical trap (MOT). It is necessary to use cold atoms to ensure that only the four intended atomic states are excited, in contrast to a Doppler broadened room temperature gas. A Kerr lens mode-locked Ti:Sapphire laser operating with an approximately 55 nm bandwidth centered at 778 nm with $f_r \approx 100$ MHz is used to excite all four transitions. $f_r$ is phase stabilized to a low phase-noise crystal oscillator, and steered via a Cesium reference to maintain the absolute frequency of the comb modes. The offset frequency $f_o$ is measured via a f-2f nonlinear interferometer and stabilized to a direct digital synthesizer. Regardless of the spectral phase of the pulses, any comb mode has an absolute frequency given by, $\nu_N = f_o + N \times f_r$, where $N$ is the mode order number (of order $10^6$ for our laser). Using prior knowledge of the $^{87}$Rb energy level structure for the 5S, 5P, and 5D hyperfine states, it is possible to select a particular $f_r$ and $f_o$ to approximate a diamond configuration with only four resonant levels (see Fig. 1(a)).

We use two values of $f_r$, the first is $f_r$=100.59660605 MHz with $f_o$=+16.94 MHz. In this case, the four resonant states are: 5S$_{1/2}$F=2, 5P$_{1/2}$F=2, 5P$_{3/2}$F=2, and 5D$_{3/2}$ F=1. With this selection of comb frequencies the transitions from 5S$_{1/2}$ F=1, the other ground state, are at least 6 MHz detuned from any intermediate and excited states. All other possible transitions are further detuned. Note that the 5S to 5P and 5D linewidths are 6 MHz and 0.66 MHz respectively. Using a slightly shifted $f_r$ of 100.59660525 MHz and the same $f_o$, the comb is resonant with the same intermediate and final states but from 5S$_{1/2}$ F=1. We indirectly measure the 5D population by counting photons from the 5D-6P-5S cascade fluorescence at 420 nm with a photomultiplier tube. The experimental cycle consists of three parts: first a MOT is formed for 6.5 ms, then the atoms are held in optical molasses for 3 ms while the magnetic field turns off, finally the atoms are excited for 0.5 ms and the photon counts are recorded versus time on a multichannel scaler. We use a standard 2f-2f configuration pulse shaper with a computer controlled spatial light modulator (SLM) to set the relative phase of the comb modes with a per pixel resolution of $\sim$150 GHz [13]. The spatial and temporal frequency chirp of the pulses at the MOT location are reduced to maximize the fringe visibility.

The first experiment provides a clear demonstration of the phase sensitive nonlinear response of the four-level

**FIG. 2:** (a) Measured interference fringes with fits under four different excitation conditions. All the results are obtained by scanning the phase $\Phi$ of the phase mask shown in Fig. 1(b). The top panels correspond to illuminating the atoms from only one direction (traveling waves). The bottom panels are under counter-propagating pulse excitation. The left panels (a) and (c) use the $f_r$ for excitation from the 5S$_{1/2}$ F=2 ground state; the right panels (b) and (d) use the $f_r$ for excitation from the 5S$_{1/2}$ F=1 ground state.
diamond configuration. We use the spatial light modulator to apply the phase mask indicated in Fig. 1(b), the effect of this mask is to change the phase of all the comb mode pairs that are resonant from the ground state to 5D_{3/2}F=1 and close to the 5P_{3/2} intermediate states (denoted by the hatched region in Fig. 1(b)). Specifically, the mask applies a variable phase step of Φ to the spectral region from 772 nm to 784 nm. Due to the aforementioned cancellation of the off-resonant amplitudes, it is sufficient to consider only the mode pairs tuned nearest to an intermediate state resonance for this first experiment.

Our measured results are shown in Fig. 2, with each fringe fit to a function of the form, \( \rho_{SD} = c_1 + c_2 \cos(\Phi + c_3)^2 \), where \( \Phi \) represents the phase applied to the SLM, \( c_3 \) is a static phase offset, and the fringe visibility is given by \( \rho_{SD} \). Due to the fact the phase mask covers both 780 nm and 776 nm, the two-photon amplitude from the resonant path through 5P_{3/2}F=2 is phase shifted by 2Φ and therefore has a period of \( \pi \) radians. The background counts due to ambient light at 420 nm and excitation of the hot Rb atoms not trapped in the MOT are measured by repeating the experiment without a MOT and subtracted from the reported data. As mentioned previously, we choose to conduct this experiment with two different values of \( f_r \). The left panels in Fig. 2 are measured with \( f_r \) set for two-photon transitions from the 5S_{1/2}F=2 ground state. The right panels are with the second \( f_r \), resonant from the 5S_{1/2}F=1 ground state. For each \( f_r \), we also measure the interference fringe under excitation from a single pulse propagation direction (Fig. 2 top panels) and under counter-propagating pulses (Fig. 2 bottom panels).

Much like an optical interferometer, two important features of our results are the fringe visibility and the phase offset. Clearly the results presented in Fig. 2 show significant differences in both the fringe visibility and phase offset as a function of excitation scheme. We begin by discussing the offset of the fringe from \( \Phi=0 \). Due to the large separation of wavelengths used in this experiment and the significant dispersion of the pulse shaper and other optics, any residual chirp of the pulse can cause an overall phase shift common to all measured fringes. However, not all fringes are shifted by the same amount; in particular, excitation from the two different ground states yields results significantly out of phase. To explain this relative phase shift we refer to Table 1, in which the key parameters to estimate the total fringe visibility and phase shift are tabulated. The first and most dominant effect is due to the sign of the dipole matrix elements; for transitions from 5S_{1/2}F=2 all the dipole moments are negative, however, for transitions from 5S_{1/2}F=1 there is a sign difference between different two-photon paths. Table 1 gives the angular part of the dipole matrix elements, \( \langle Lm_F|\hat{r}|L'm'_F \rangle \), denoted as \( \mu_{g1} \) and \( \mu_{f} \). Clearly the sign of the matrix elements affect the interference in closed loop excitation, an important consideration for phase-resolved two-dimensional spectroscopy [14].

It is also necessary to consider the phase shift of a particular two-photon amplitude due to the detuning from the relevant intermediate state. For this we include in Table 1 the path through the additional intermediate state 5P_{1/2}F=1, although the nearest comb mode is detuned, the dipole moment is sufficiently large to make its contribution significant. Due to the detuning of this transition path, there is a large phase shift of the corresponding amplitude. The effect of this additional path through 5P_{1/2}F=1 is to phase shift the total transition amplitude via 5P_{1/2} relative to the 5P_{3/2} amplitude, and thus the fringe shift. This occurs for two-photon transitions from both ground states. However, as can be seen from the dipole moments and amplitudes in Table 1, the effect of the 5P_{1/2}F=1 state is less for the 5S_{1/2}F=1 ground state case. The difference in fringe shift between Fig. 2(a) and (b), corresponding to excitation from the two ground states, is 54°. This is in good agreement with the theoretically predicted value of 56°.

The second feature, the fringe visibility, is a result of the coherent interference between the 5P_{1/2} and 5P_{3/2} paths in the diamond configuration and any additional incoherent signal which raises the measured fringe minimum. Referring to the results in Fig. 2, the fringe visibility is strongly reduced under standing wave excitation and exhibits little dependence on the choice of ground state. In the case of traveling wave excitation, all the atoms in the MOT are excited by the same relative magnitude of electric fields. The visibility predicted using the amplitudes presented in Table 1 is 82% for excitation from the 5S_{1/2}F=2 ground state and 92% for the 5S_{1/2}F=1 ground state, assuming equal population distribution among the \( m_F \) sublevels. The best experimental results obtained for the visibility are about 70%, shown in Fig. 2(a) and (b). Residual frequency and spatial chirps have likely lowered the observed visibility from the ideal case. For traveling wave excitation the interference effect is observed for only the first 50 μs of excitation.

| Intermediate | \( \mu_{g1} \) | \( \mu_{f} \) | \( \Delta \) (MHz) | \( \epsilon_{gf} \) | \( \theta \) |
|--------------|--------------|--------------|----------------|----------------|-------------|
| 5P_{3/2}F=2 | -0.17        | -0.07        | 0.2            | 3.0            | -3.8°       |
| 5P_{1/2}F=2 | -0.17        | -0.09        | 0.4            | 3.4            | -7.6°       |
| 5P_{1/2}F=1 | -0.29        | -0.26        | -11.5          | 4.3            | 75.4°       |

TABLE I: Left column is the intermediate state for each two-photon transition with a resonant or near-resonant comb mode. Across the top are: the reduced dipole moments, the detuning of the nearest mode from the intermediate state, the relative magnitude of the two-photon amplitude, and the phase of the amplitude. The top section is for transitions from 5S_{1/2}F=2 and the bottom from 5S_{1/2}F=1.
FIG. 3: (a) Measured signal enhancement. The ratio of signals with and without the phase mask in (b), versus position of the SLM in the spectrum. The zero of the offset frequency is chosen to be the position of the maximum signal increase. (b) The applied phase mask is indicated by the hatched region. Exactly π radians of phase is applied just below 762 nm and 776 nm to add an extra phase shift to those mode pairs that join in the hatched region.

after which the atoms are Doppler shifted completely off of resonance due to radiation pressure. It is for this reason the data presented in Fig. 2 is only the first 10 µs of excitation; using a larger time window significantly reduced the fringe visibility.

One method to reduce the effect of radiation pressure on the atoms is to balance the average force by probing with counter-propagating pulses [6]. The bottom panels of Fig. 2 present the fringe measured using well overlapped counter-propagating beams of the same intensity. Although we measure a constant fringe visibility in this case for an extended time of 300 µs, the multi-mode standing wave generated by the counter-propagating pulses reduces the visibility to ~25%. This effect arises because the four main resonance frequencies have different wavelengths and thus different standing-wave periods, so the magnitudes of the four resonant electric fields vary spatially. For example, in some regions of the atom cloud the 780 nm field is maximum while the 794 nm field is minimum, and there is no interference effect. In this case a spatial average over the atom cloud, taking into account the different standing waves, must be conducted. Using the amplitudes given in Table 1, the visibility under multimode standing wave excitation is 36% and 44% from the $F=2$ and $F=1$ ground states, respectively.

The first experiment focuses entirely on those comb modes near an intermediate resonance. This is due to the fact that the vast majority of modes cancel out and thus make no net contribution to the two-photon amplitude. In the second experiment, we use $f_o$ and $f_f$ for two-photon transitions from the $5S_{1/2}F=2$ ground state and apply the phase mask presented in Fig. 3(b). This phase mask forces constructive interference between the amplitudes due to the off-resonant mode pairs, increasing the total signal. Recall for every two-photon resonant mode pair detuned below an intermediate state, there is a pair detuned approximately equally above the state. For a transform-limited pulse train, these two pairs of modes give rise to excited state amplitudes that are equal and opposite, and therefore cancel to zero. By applying the phase mask in Fig. 3(b), those modes that are detuned below either the $5P_{3/2}$ or $5P_{1/2}$ states (the hatched area in Fig. 3(b)) obtain a 180° phase shift with respect to those detuned above the intermediate state. This type of spectral phase negates the inherent phase change due to the detuning around a resonance (see Eq. 1), and causes constructive interference. Figure 3(a) shows we achieve a maximum increase of 2.56 over the normal signal. The theoretical enhancement is 2.85, however, this estimate does not include the effects of diffraction at the phase steps in the SLM, which likely reduces the maximum. This data is obtained by first coarsely tuning the position of the phase mask at the per-pixel resolution. Then for finer control of the location of the phase step applied to the comb spectrum, the entire SLM is shifted using a micrometer through the spectrally dispersed optical field.

In conclusion, we have demonstrated the precise control of a diamond configuration four-level atomic coherence over a 32 nm spectral width. The first experiment focuses on the comb modes resonant with intermediate states, and the second optimizes the two-photon transition rate using high-resolution spectral phase shaping to force constructive interference between the off-resonant modes. The demonstrated ability in high-resolution control of the coherence of a four-level system over a very broad-bandwidth may enable future research in nonlinear optics of multi-level systems. For example, one proposal for a cw-VUV laser utilizes lasing without inversion in a four-level diamond configuration
