Abstract

We study bifurcations associated with stability of the lowest stationary point (SP) of a damped parametrically forced pendulum by varying $\omega_0$ (the natural frequency of the pendulum) and $A$ (the amplitude of the external driving force). As $A$ is increased, the SP will restabilize after its instability, destabilize again, and so ad infinitum for any given $\omega_0$. Its destabilizations (restabilizations) occur via alternating supercritical (subcritical) period-doubling bifurcations (PDB’s) and pitchfork bifurcations, except the first destabilization at which a supercritical or subcritical bifurcation takes place depending on the value of $\omega_0$. For each case of the supercritical destabilizations, an infinite sequence of PDB’s follows and leads to chaos. Consequently, an infinite series of period-doubling transitions to chaos appears with increasing $A$. The critical behaviors at the transition points are also discussed.

I. INTRODUCTION

A damped parametrically forced pendulum (DPFP) with a vertically oscillating support is investigated. It can be described by a second-order non-autonomous ordinary differential equation (ODE) \[1–3\],

\[\ddot{x} + 2\pi\gamma\dot{x} + 2\pi(\omega_0^2 - A\cos 2\pi t)\sin 2\pi x = 0,\]  \hspace{1cm} (1)

where \(x\) is the angular position, \(\gamma\) the damping coefficient, \(\omega_0\) the undamped natural frequency of the unforced pendulum, and \(A\) the amplitude of the external driving force of period one. The overdot denotes the differentiation with respect to time, and all variables and parameters are expressed in dimensionless forms.

The DPFP, albeit looking simple, shows a richness in its dynamical behavior. As the amplitude \(A\) is increased up to moderate values, transitions from periodic attractors to chaotic attractors and \textit{vice versa}, coexistence of different attractors, transient chaos, and so on have been found numerically \[4–6\] and analytically \[7\]. They have been also observed in real experiments \[8,9\]. However, as \(A\) increases further, the DPFP exhibits new interesting dynamical behaviors not found in previous works, as will be seen below.

Here we are interested in bifurcations associated with stability of the lowest stationary point (SP) with \(x = 0\) and \(\dot{x} = 0\) of the DPFP. The linear stability of the SP is determined by the linearized equation

\[\ddot{x} + 2\pi\gamma\dot{x} + 4\pi^2(\omega_0^2 - A\cos 2\pi t)x = 0,\]  \hspace{1cm} (2)

which is a damped Mathieu equation. For the undamped case with \(\gamma = 0\), stability properties of the Mathieu equation are given in \[10,11\]. There exist an infinite number of disconnected instability regions of the SP in the \(\omega_0 - A\) plane. These instability regions may be called “tongues”, because their lower parts are of tongue shape (see Fig. 7-5 in Ref. \[11\]). They can be also labelled by an integer \(n\), half of which correspond, in absence of forcing \((A = 0)\), to parametric resonant values of \(\omega_0\), i.e. \(\omega_0 = \frac{n}{2}\). However, even a small amount of damping
leads to the presence of a non-zero threshold value $A_t(n)$ of the amplitude necessary for the occurrence of the $n$th-order parametric resonance \cite{[1–3]}. Moreover, $A_t(n)$ grows rapidly with increasing $n$ (see Fig. 100 in Ref. \cite{[2]}).

We first introduce the Poincaré map for the DPFP in Sec. \[I\] and then discuss various bifurcations associated with stability of periodic orbits. With increasing $A$ to sufficiently large values, the bifurcation behaviors associated with stability of the SP are investigated in Sec. \[II\] for a moderately damped case with $\gamma = 0.1$. The damped Mathieu Eq. (2) has an infinity of alternating stable and unstable $A$ ranges for any given $\omega_0$. Hence, as $A$ is increased, the SP undergoes a cascade of “resurrections” for any given $\omega_0$, i.e. it will restabilize after it loses its stability, destabilize again, and so ad infinitum. Its restabilizations occur through alternationg subcritical period-doubling bifurcations (PDB’s) and pitchfork bifurcations (PFB’s). On the other hand, the destabilizations occur through alternating supercritical PDB’s and PFB’s, except the first destabilization at which a supercritical or supercritical bifurcation takes place depending on the value of $\omega_0$. For each case of the supercritical destabilizations, an infinite sequence of PDB’s leading to chaos follows. Consequently, an infinite series of period-doubling transitions to chaos appears with increasing $A$, which was not found in previous works. This is in contradistinction to the cases of the one-dimensional (1D) maps and other damped forced oscillators, for which only one single period-doubling transition to chaos occurs. In Sec. \[IV\], we study the critical scaling behaviors at the transition points. It is found that they are the same as those for the 1D maps. Finally, a summary is given in Sec. \[V\].

\section{II. STABILITY OF PERIODIC ORBITS, BIFURCATIONS AND LYAPUNOV EXPONENTS IN THE POINCARÉ MAP}

In this section, we first discuss stability of period orbits in the Poincaré map of the DPFP, using the Floquet theory. Bifurcations associated with the stability and Lyapunov exponents are then discussed.
The second-order ODE (1) is reduced to two first-order ODE’s:

\[ \dot{x} = y, \quad (3a) \]
\[ \dot{y} = -2\pi \gamma y - 2\pi (\omega_0^2 - A \cos 2\pi t) \sin 2\pi x. \quad (3b) \]

The Poincaré maps of an initial point \( z_0 \equiv (x(0), y(0)) \) can be computed by sampling the points \( z_m \) at the discrete time \( t = m \), where \( m = 1, 2, 3, \ldots \). We call the transformation \( z_m \to z_{m+1} \) the Poincaré (time-1) map, and write \( z_{m+1} = P(z_m) \).

The Poincaré map \( P \) has the inversion symmetry such that

\[ SPS(z) = P \text{ for all } z, \quad (4) \]

where \( z = (x, y) \), \( S \) is the inversion of \( z \), i.e., \( S(z) = -z \). If an orbit \( \{z_m\} \) of \( P \) is invariant under \( S \), then it is called a symmetric orbit. Otherwise, it is called an asymmetric orbit, and has its “conjugate” orbit \( S\{z_m\} \).

We now study the stability of a periodic orbit with period \( q \) such that \( P^q(z_0) = z_0 \) but \( P^j(z_0) \neq z_0 \) for \( 1 \leq j \leq k - 1 \). Here \( P^k \) means the \( k \)-times iterated map. The linear stability of the \( q \)-periodic orbit is determined from the linearized-map matrix \( DP^q(z_0) \) of \( P^q \) at an orbit point \( z_0 \). Using the Floquet theory \([12]\), the matrix \( DP^q \) can be obtained by integrating the linearized differential equations for small perturbations as follows.

Let \( z^*(t) = z^*(t+q) \) be a solution lying on the closed orbit corresponding to the \( q \)-periodic orbit. In order to determine the stability of the closed orbit, we consider an infinitesimal perturbation \( (\delta x(t), \delta y(t)) \) to the closed orbit. Linearizing Eq. (3) about the closed orbit, we obtain

\[ \begin{pmatrix} \delta \dot{x} \\ \delta \dot{y} \end{pmatrix} = J(t) \begin{pmatrix} \delta x \\ \delta y \end{pmatrix}, \quad (5) \]

where

\[ J(t) = \begin{pmatrix} 0 & 1 \\ -4\pi^2 (\omega_0^2 - A \cos 2\pi t) \cos 2\pi x^*(t) & -2\pi \gamma \end{pmatrix}. \quad (6) \]
Note that $J$ is a $2 \times 2$ $q$-periodic matrix. Let $W(t) = (w^1(t), w^2(t))$ be a fundamental solution matrix with $W(0) = I$. Here $w^1(t)$ and $w^2(t)$ are two independent solutions expressed in column vector forms, and $I$ is the $2 \times 2$ unit matrix. Then a general solution of the $q$-periodic system has the following form

$$
\begin{pmatrix}
\delta x(t) \\
\delta y(t)
\end{pmatrix} = W(t) \begin{pmatrix}
\delta x(0) \\
\delta y(0)
\end{pmatrix}.
$$

(7)

Substitution of Eq. (7) into Eq. (5) leads to an initial-value problem to determine $W(t)$

$$
\dot{W}(t) = J(t)W(t), \quad W(0) = I.
$$

(8)

It is clear from Eq. (7) that $W(q)$ is just the linearized-map matrix $DP^q(z_0)$. Hence the matrix $DP^q$ is calculated through integration of Eq. (8) over the period $q$.

The characteristic equation of the linearized-map matrix $M(\equiv DP^q)$ is

$$
\lambda^2 - \text{tr}M \lambda + \text{det} M = 0,
$$

(9)

where $\text{tr} M$ and $\text{det} M$ denote the trace and determinant of $M$, respectively. The eigenvalues, $\lambda_1$ and $\lambda_2$, of $M$ are called the Floquet stability multipliers. As shown in [13], $\text{det} M$ is calculated from a formula

$$
\text{det} M = e^{\int_0^q \text{tr} J dt}.
$$

(10)

Substituting the trace of $M$ (i.e., $\text{tr} J = -2\pi \gamma$) into Eq. (10), we obtain

$$
\text{det} M = e^{-2\pi \gamma q}.
$$

(11)

Hence, the Poincaré map $P$ is a two-dimensional (2D) dissipative map with a constant Jacobian determinant (less than unity), like the Hénon map [14].

The pair of stability multipliers of a periodic orbit lies either on the circle of radius $e^{-\pi \gamma q}$, or on the real axis in the complex plane. The periodic orbit is stable only when both multipliers lie inside the unit circle. We first note that they never cross the unit circle, and
hence Hopf bifurcations do not occur. Consequently, it can lose its stability only when a multiplier decreases (increases) through $-1$ (1) on the real axis.

A more convenient real quantity $R$, called the residue and defined by,

$$R \equiv \frac{1 + \det M - \text{tr} M}{2(1 + \det M)},$$

was introduced in \cite{15} to characterize stability of periodic orbits in 2D dissipative maps with constant Jacobian determinants. A periodic orbit is stable when $0 < R < 1$; at both ends of $R = 0$ and 1, the stability multipliers $\lambda$’s are 1 and $-1$, respectively. When $R$ decreases through 0 (i.e., $\lambda$ increases through 1), the periodic orbit loses its stability via saddle-node or pitchfork or transcritical bifurcation. On the other hand, when $R$ increases through 1 (i.e., $\lambda$ decreases through $-1$), it becomes unstable via PDB, also referred to as a flip or subharmonic bifurcation. For each case of the PFB’s and PDB’s, two types of supercritical and subcritical bifurcations occur. For more details on bifurcations, refer to Ref. \cite{16}.

Lyapunov exponents of an orbit $\{z_m\}$ in the Poincaré map $P$ characterize the mean exponential rate of divergence of nearby orbits \cite{17}. There exist two Lyapunov exponents $\sigma_1$ and $\sigma_2$ ($\sigma_1 \geq \sigma_2$) such that $\sigma_1 + \sigma_2 = -2\pi \gamma$, because the linearized Poincaré map $DP$ has a constant Jacobian determinant, $\det DP = e^{-2\pi \gamma}$. We choose an initial perturbation $\delta z_0$ to the initial orbit point $z_0$ and iterate the linearized map $DP$ for $\delta z$ along the orbit to obtain the magnitude $d_m (\equiv |\delta z_m|)$ of $\delta z_m$. Then, for almost all infinitesimally-small initial perturbations, we have the largest Lyapunov exponent $\sigma_1$ given by

$$\sigma_1 = \lim_{m \to \infty} \frac{1}{m} \ln \frac{d_m}{d_0}. \tag{13}$$

If $\sigma_1$ is positive, then the orbit is called a chaotic orbit; otherwise, it is a regular orbit.

III. MULTIPLE PERIOD-DOUBLING TRANSITIONS TO CHAOS

In this section, by varying two parameters $\omega_0$ and $A$, we study bifurcations associated with stability of the SP of the DPFP for a moderately damped case with $\gamma = 0.1$. It is found
that with increasing $A$, the SP undergoes an infinite series of period-doubling transitions to chaos for any given $\omega_0$. This is in contrast to 1D maps and other damped forced oscillators with only single period-doubling transition to chaos.

The stability diagram of the SP is given in Fig. 1. There exist an infinity of disconnected instability regions in the $\omega_0$-$A$ plane, which are separated by one connected stability region. The instability regions may be called “tongues”, because their lower parts are tongue-shaped. They can be also labelled by an integer $n$, half of which correspond to the parametric resonant values of $\omega_0$ (i.e., $\omega_0 = \frac{n}{2}$) in absence of forcing ($A = 0$) for the undamped case of $\gamma = 0$ [1–3,10,11]. However, even a small amount of damping results in a non-zero minimal value $A_t(n)$ of the amplitude necessary for the occurrence of the $n$th-order parametric resonance [1–3]. Furthermore, $A_t(n)$ grows rapidly with increasing $n$ (see Fig. 1). Hereafter, each tongue of order $n$ is denoted by $T_n$.

With increasing $A$, each tongue $T_n$ is twisted to the left, and lies above the tongue $T_{n-1}$. In such a way, tongues pile up successively, as shown in Fig. 1. Consequently, there exist an infinity of alternating stable and unstable $A$ ranges for any given $\omega_0$. Hence, as $A$ is increased, the SP will restabilize after it loses its instability, destabilize again, and so ad infinitum for any given $\omega_0$. Such “resurrection” mechanisms are given below.

Bifurcation behaviors at the tongue boundaries are investigated in details. They depend on whether the tongue-order $n$ is odd or even. At the tongue boundaries of odd (even) order $n$, the residue of the SP is 1 (0). Consequently, PDB’s and PFB’s occur when tongue boundaries of odd and even order $n$ are crossed, respectively. For example, the boundaries of $T_1$ and $T_3$ in Fig. 1 are PDB curves, while the boundary of $T_2$ is a PFB curve. For the cases of PDB’s and PFB’s, there are two types of supercritical and subcritical bifurcations, which occur depending on where tongue boundaries are crossed. A saddle-node bifurcation (SNB) curve, at which a pair of stable and unstable orbits with period 2 (1) is born, touches each tongue boundary of odd (even) order $n$ at a boundary point $[\omega_b(n), A_b(n)]$, and decomposes it into the supercritical and subcritical parts. As an example, see the three SNB curves, denoted by dash-dotted curves, touching the boundaries of $T_1$, $T_2$, and $T_3$, respectively,
in Fig. [1]. On the lower left part of each tongue boundary, denoted by a solid curve, a supercritical bifurcation occurs. The remaining subcritical boundary curve starting from \([\omega_b(n), A_b(n)]\) first goes to the right, but it turns left at a point \([\omega_t(n), A_t(n)]\). It consists of two types of subparts, denoted by short-dotted and dashed curves, on which a subcritical bifurcation takes place. On the subcritical segment with \(\omega_b(n) < \omega_0 < \omega_t(n)\), the SP absorbs an unstable orbit born at a dash-dotted SNB curve and loses its stability. On the other hand, the stable orbit born by the same SNB undergoes an infinite series of PDB’s leading to chaos. The accumulation points of such PDB’s are denoted by open circles in Fig. [1].

When the SP loses its stability via supercritical PDB’s and PFB’s, the system is asymptotically attracted to periodic attractors (born by the supercritical bifurcations) with the doubled period and the same period, respectively. However, for the subcritical bifurcation cases, the asymptotic states just after the instability of the SP may be periodic or chaotic, depending on which subparts of the subcritical boundaries are crossed. In Fig. [2], we fix different \(\omega_0\) and increase \(A\) to cross different subparts of a subcritical boundary of \(T_1\). When a short-dotted boundary curve is crossed, the asymptotic state becomes periodic [see Fig. 2(a)], because the SP jumps to a periodic attractor born by an SNB after its instability. For this periodic case, with increasing \(A\) an infinite sequence of supercritical PDB’s leading to small-scale chaos follows. However, when a dashed boundary is crossed, large-scale full chaos appears via intermittency [18], and hence the asymptotic state becomes chaotic [see Fig. 2(b)].

With increasing \(A\) to sufficiently large values, the bifurcation behaviors associated with stability of the SP are investigated in details for many values of \(\omega_0\). For a given \(\omega_0\), the restabilizations of the SP occur via alternating subcritical PDB’s and PFB’s with increasing \(A\), as shown in Fig. [1]. On the other hand, the destabilizations take place via alternating supercritical PDB’s and PFB’s, except the first destabilization at which a supercritical or subcritical bifurcation occurs depending on the value of \(\omega_0\) (e.g., for \(\omega_0 = 0.5\) (0.65), the first destabilization occurs via supercritical (subcritical) PDB). For each case of the
supercritical destabilizations, an infinite sequence of supercritical PDB’s leading to a pair of chaotic attractors follows and ends at a finite accumulation point. In each tongue, such accumulation points of PDB’s, denoted by solid circles in Fig. 1, seem to form a smooth critical line. Consequently, an infinite series of period-doubling transitions to chaos appears with increasing $A$. This is in contradistinction to the 1D maps and other damped forced oscillators, in which only single period-doubling transition to chaos occurs.

As an example of the multiple period-doubling transitions to chaos, consider the case $\omega_0 = 0.5$. A bifurcation diagram along the vertical line $\omega_0 = 0.5$ is shown in Fig. 3. Through a supercritical PDB, the SP loses its stability at its first destabilization point $A_d(1) = 0.100218 \cdots$, and a symmetric orbit of period 2 is born. Unlike the case of the SP, the symmetric 2-periodic orbit becomes unstable by a symmetry-breaking supercritical PFB, which leads to the birth of a conjugate pair of asymmetric orbits with period 2. (For the sake of convenience, only one asymmetrical orbit of period 2 is shown in Fig. 3.) However, as $A$ is further increased, an infinite sequence of supercritical PDB’s follows and ends at its accumulation point $A_1^* (= 0.35770984 \cdots)$. The critical scaling behaviors of period doublings near the critical point $A_1^*$ are the same as those for the 1D maps, as will be seen in Sec. [VI].

After the period-doubling transition to chaos, a conjugate pair of small chaotic attractors with positive largest Lyapunov exponent $\sigma_1$ appear. As $A$ is increased, the different parts of a chaotic attractor coalesce and form larger pieces. For example, the chaotic attractor with $\sigma_1 \simeq 0.091$ shown in Fig. 4(a) seems to be composed of four distinct pieces for $A = 0.3579$. As shown in Fig. 4(b), these pieces coalesce to form two large pieces with $\sigma_1 = 0.158$ for $A = 0.3582$. However, beyond some critical point $A_c(1) (\simeq 0.3586)$, the chaotic attractor becomes unstable, and the system is asymptotically attracted to a rotational orbit of period 1 born by an SNB. For $A > A_c(1)$, the DPFP continues to exhibit rich dynamical behaviors. With increasing $A$, birth of new periodic attractors via SNB’s, transitions from periodic attractors to chaotic attractors and vice versa, coexistence of different attractors, and so on are found until the SP restabilizes. (For more details on such dynamical behaviors,
refer to previous works \cite{4-9}. However, with increasing $A$ further, the DPFP exhibits new interesting dynamical behaviors not previously found.

When the dashed subcritical boundary of $T_1$ is crossed at the first restabilization point $A_r(1) (= 3.150509\cdots)$, the SP restabilizes via subcritical PDB. An “inverse” process of the case of Fig. 2(b) occurs. There exists large-scale full chaos below $A_r(1)$. When $A$ increases through $A_r(1)$, the large chaotic attractor disappears, and the restabilization of the SP occurs with birth of a new unstable 2-periodic orbit. The residue $R$ of the SP decreases monotonically from one, and becomes zero at the second destabilization point $A_d(2) (= 3.224230\cdots)$ on the supercritical PFB curve of $T_2$.

A second bifurcation diagram for $\omega_0 = 0.5$ is shown in Fig. 5. The SP becomes unstable via symmetry-breaking supercritical PFB at its second destabilization point $A_d(2)$, which results in the birth of a conjugate pair of asymmetric orbits with period 1. With further increase of $A$, a second infinite sequence of supercritical PDB’s follows and ends at its accumulation point $A^*_2 (= 3.26370315\cdots)$. The critical scaling behaviors of period doublings near $A = A^*_2$ are the same as those near the first accumulation point $A^*_1$. After the second period-doubling transition to chaos, a conjugate pair of small chaotic attractors also appears. They persist until some critical point $A_c(2) (\simeq 3.263862)$, beyond which the system is asymptotically attracted to an oscillating 2-periodic orbit born via SNB. As in the tongue of order 1, the DPFP exhibits diverse dynamical behaviors such as transitions between the periodic and chaotic attractors and the coexistence of different attractors in the region between $A_c(2)$ and the second restabilization point $A_r(2) (= 10.093985\cdots)$.

When the dashed subcritical boundary of $T_2$ is crossed at $A_r(2)$, a subcritical PFB occurs. Consequently, the SP restabilizes with birth of a new unstable orbit of period 1. As $A$ is further increased, the residue $R$ of the SP monotonically increases, and becomes one at the third destabilization point $A_d(3) (= 10.097583\cdots)$ on the supercritical PDB curve of $T_3$. Since the order of $T_3$ is odd, the subsequent bifurcation behaviors in $T_3$ are the same as those for the case of $T_1$. That is, a third infinite sequence of supercritical PDB’s, leading to a pair of small chaotic attractors, follows and ends at its accumulation point $A^*_3$.
This third bifurcation diagram for $\omega_0 = 0.5$ is given in Fig. [3]. The critical scaling behaviors of period doublings near $A^*_3$ are also the same as those near $A^*_1$, as will be seen in the next section.

We have also studied many other cases with different $\omega_0$, and found multiple period-doubling transitions to chaos with increasing $A$. Such accumulation points are denoted by solid circles in Fig. [3]. In each tongue of order $n$, they form a smooth critical line $A^*_n(\omega_0)$. Since the range of $\omega_0$ is $0 < \omega_0 < \omega_b(n)$, each critical line of order $n$ ends inside the tongue with order $n$. As mentioned above, a stable periodic orbit, born at a dash-dotted SNB curve, also undergoes an infinite sequence of supercritical PDB’s. The accumulation points of such PDB’s, denoted by open circles in Fig. [3] form another critical line. The two different critical lines joins at a point with $\omega_0 = \omega_b(n)$. Consequently, each critical line of order $n$ extends to the outside of the tongue of order $n$.

IV. CRITICAL BEHAVIORS OF PERIOD-DOUBLING BIFURCATIONS

In this section, we study the critical behaviors (CB’s) of PDB’s for many values of $\omega_0$. The orbital scaling behavior and the power spectra of the periodic orbits born via PDB’s as well as the parameter scaling behavior are particularly investigated. The CB’s for all cases studied are found to be the same as those for the 1D maps.

As an example, we consider the case $\omega_0 = 0.5$. The first three period-doubling transition points $A^*_i$’s ($i = 1, 2, 3$) are shown in Fig. [3]. Only the CB’s near $A^*_1$ are given below, because the CB’s at the three transition points are the same. For this case, we follow the periodic orbits of period $2^k$ up to level $k = 8$. As explained above, for $A = A_d(1)$, the SP becomes unstable via supercritical PDB and a new symmetric 2-periodic orbit appears (see Fig. 3). However, the symmetric orbit of period 2 loses its stability by a supercritical symmetry-breaking PFB at $A = 0.335257 \cdots$. As a result, a conjugate pair of asymmetric 2-periodic orbits appears. As $A$ is further increased, each asymmetrical orbit with period 2 undergoes an infinite sequence of supercritical PDB’s, ending at its accumulation point $A^*_1$.\[11]
Table I gives the $A$-values at which the supercritical PDB's take place; at $A_k$, the residue $R_k$ of an asymmetric orbit of period $2^k$ is one. The sequence of $A_k$ converges asymptotically geometrically to its limit value $A^*_1$ with ratio $\delta$: 

$$\delta_k = \frac{A_k - A_{k-1}}{A_{k+1} - A_k} \rightarrow \delta. \quad (14)$$

The sequence of $\delta_k$ is also listed in Table I. Note that its limit value $\delta (\approx 4.67)$ agrees well with that ($= 4.669 \cdots$) for a 1D map $x_{m+1} = f(x_m)$ with a single quadratic maximum $x^*$. We also obtain the value of $A^*_1 (= 0.3577098453)$ by superconverging the sequence of $\{A_k\}$.

For the 1D map $f$, consider a $2^k$-periodic orbit point $x^{(k)}$ nearest to the maximum point $x^*$ when the orbit becomes unstable. Then, the sequence of $x^{(k)}$ also converges asymptotically geometrically to the maximum point $x^*$ with ratio $\alpha = -2.502 \cdots$. Note that the region near the maximum point $x^*$ is the most rarified region, because the distance between $x^{(k)}$ and its nearest orbit point $f^{2^k-1}(x^{(k)})$ is maximum. Hence, for the case of the Poincaré map $P$, we first locate the most rarified region by choosing an orbit point $z^{(k)} [= (x^{(k)}, y^{(k)})]$ which has the largest distance from its nearest orbit point $P^{2^k-1}(z^{(k)})$ for $A = A_k$. The two sequences $\{x^{(k)}\}$ and $\{y^{(k)}\}$ are listed in Table I. Note that they converge asymptotically geometrically to their limit values $x^*$ and $y^*$ with the 1D ratio $\alpha$.

$$\alpha_{x,k} = \frac{x^{(k)} - x^{(k-1)}}{x^{(k+1)} - x^{(k)}} \rightarrow \alpha, \quad \alpha_{y,k} = \frac{y^{(k)} - y^{(k-1)}}{y^{(k+1)} - y^{(k)}} \rightarrow \alpha. \quad (15)$$

The values of $x^* (= 0.091126)$ and $y^* (= 0.735292)$ are also obtained by superconverging the sequences of $x^{(k)}$ and $y^{(k)}$, respectively.

We also study the power spectra of the $2^k$-periodic orbits ($k = 1, \ldots, 8$) at the PDB points $A_k$. Consider the orbit of level $k$ whose period is $q = 2^k$, $\{z^{(k)}_m = (x^{(k)}_m, y^{(k)}_m), \ m = 0, 1, \ldots, q - 1\}$. Then, the $j$th Fourier component of this $2^k$-periodic orbit is given by

$$z^{(k)}(\omega_j) = \frac{1}{q} \sum_{m=0}^{q-1} z^{(k)}_m e^{-i\omega_j m}, \quad (16)$$

where $\omega_j = 2\pi j/q$, and $j = 0, 1, \ldots, q - 1$. The power spectrum $P^{(k)}(\omega_j)$ of level $k$ defined by
\[ P^{(k)}(\omega_j) = |z^{(k)}(\omega_j)|^2, \]

has discrete peaks at \( \omega = \omega_j \). In the power spectrum of the next \((k + 1)\) level, new peaks of the \((k + 1)\)th generation appear at odd harmonics of the fundamental frequency, \( \omega_j = 2\pi(2j + 1)/2^{(k+1)} \) \((j = 0, \ldots, 2^k - 1)\). To classify the contributions of successive PDB’s in the power spectrum of level \( k \), we write

\[ P^{(k)} = P_{00} \delta(\omega) + \sum_{l=1}^{k} \sum_{j=0}^{2^{(l-1)}-1} P_{lj}^{(k)} \delta(\omega - \omega_{lj}), \]

where \( P_{lj}^{(k)} \) is the height of the \( j \)th peak of the \( l \)th generation appearing at \( \omega = \omega_{lj} \) \((\equiv 2\pi(2j + 1)/2^l)\). As an example, see the power spectrum \( P^{(8)}(\omega) \) of level 8 shown in Fig. [7].

The average height of the peaks of the \( l \)th generation is given by

\[ \phi^{(k)}(l) = \frac{1}{2^{l-1}} \sum_{j=0}^{2^{l-1}-1} P_{lj}^{(k)}. \]

It is of interest whether the sequence of the ratios of the successive average heights

\[ 2\beta^{(k)}(l) = \phi^{(k)}(l)/\phi^{(k)}(l + 1), \]

converges. The ratios are listed in Table [14]. They seem to approach a limit value, \( 2\beta \approx 21 \), which agrees well with that \((= 20.96 \cdots)\) for the 1D map [22].

V. SUMMARY

Bifurcations associated with stability of the SP of the DPFP are investigated by varying two parameters \( \omega_0 \) and \( A \). As \( A \) is increased, the SP undergoes an infinite sequence of alternating restabilizations and destabilizations for any given \( \omega_0 \). The restabilization and destabilization mechanisms are also given in details. A new finding is that an infinite series of period-doubling transitions to chaos appears with increasing \( A \), which was not found in previous works. This is in contradistinction to the cases of the 1D maps and other damped forced oscillators with only single period-doubling transition. The critical scalings at the transition points are also found to be the same as those of the 1D maps.

FIGURES

FIG. 1. Stability diagram of the SP of the DPFP. There exist an infinity of “tongues” $T_n$ of instability regions. For each tongue, a supercritical bifurcation occurs on the solid boundary curve, whereas a subcritical bifurcation takes place on the remaining dashed or short-dotted boundary curve. There are also SNB curves touching the tongue boundaries, which are denoted by the dash-dotted curves. The accumulation points of PDB’s, denoted by solid and open circles, form critical lines. For other details, see the text.

FIG. 2. Asymptotic states after the instability of the SP via subcritical bifurcations. A pair of symmetric stable and unstable orbit of period 2 are born via an SNB. The $x$-positions of the stable and unstable orbits are denoted by the solid and dashed curves, respectively. At a subcritical PDB point, the SP, whose $x$-position is denoted by the dotted line, loses its stability by absorbing the unstable 2-periodic orbit. After its instability, (a) the SP jumps to the stable 2-periodic orbit for $\omega_0 = 0.55$, whereas (b) large-scale full chaos appears for $\omega_0 = 0.6832$. Note also that for each case, the stable 2-periodic orbit undergoes an infinite sequence of PDB’s leading to small-scale chaos.

FIG. 3. First bifurcation diagram for $\omega_0 = 0.5$. The SP2 and ASP2 denote the stable A-ranges of the symmetric and asymmetric orbits of period 2, respectively. The PN also designates the stable A-range of the asymmetric periodic orbit with period N ($N=4, 8, 16$).

FIG. 4. Chaotic attractors after the first period-doubling transition to chaos. (a) For $A = 0.3579$, the chaotic attractor with the largest Lyapunov exponent $\sigma_1 \simeq 0.091$ is composed of four pieces. (b) These pieces merge to form two large pieces with $\sigma_1 \simeq 0.158$ for $A = 0.3582$.

FIG. 5. Second bifurcation diagram for $\omega_0 = 0.5$. The ASP1 and PN denote the stable A-ranges of the asymmetric orbit of period 1 and N ($N=2, 4, 8, 16$), respectively.

FIG. 6. Third bifurcation diagram for $\omega_0 = 0.5$. The SP2 and ASP2 denote the stable A-ranges of the symmetric and asymmetric orbits of period 2, respectively. The PN also designates the stable A-range of the asymmetric periodic orbit with period N ($N=4, 8, 16$).
FIG. 7. Power spectrum $P^{(8)}(\omega)$ of level 8 for $A = A_8$ ($= 0.357709779136$)
