Parameterized Streaming Algorithms for Vertex Cover

Friday 25th July, 2014

Abstract

As graphs continue to grow in size, we seek ways to effectively process such data at scale. The model of streaming graph processing, in which a compact summary is maintained as each edge insertion/deletion is observed, is an attractive one. However, few results are known for optimization problems over such dynamic graph streams.

In this paper, we introduce a new approach to handling graph streams, by instead seeking solutions for the parameterized versions of these problems where we are given a parameter $k$ and the objective is to decide whether there is a solution bounded by $k$. By combining kernelization techniques with randomized sketch structures, we obtain the first streaming algorithms for the parameterized versions of the Vertex Cover problem. We consider two models for a graph stream on $n$ nodes: the insertion-only model where the edges can only be added, and the dynamic model where edges can be both inserted and deleted. More formally, we show the following results:

- In the insertion only model, there is a one-pass deterministic algorithm for the parameterized Vertex Cover problem which computes a sketch using $\tilde{O}(k^2)$ space such that at each timestamp in time $\tilde{O}(2^{k^2})$ it can either extract a solution of size at most $k$ for the current instance, or report that no such solution exists.

- In the dynamic model, and under the promise that at each timestamp there is a solution of size at most $k$, there is a one-pass algorithm for the parameterized Vertex Cover problem which computes a sketch using $O(k^2)$ space such that in time $\tilde{O}(2^{k^2})$ it can extract a solution for the final instance with probability $1 - \delta/n^{O(1)}$, where $\delta < 1$. To the best of our knowledge, this is the first graph streaming algorithm that combines linear sketching with sequential operations that depend on the graph at the current time.

- In the dynamic model without any promise, there is a one-pass randomized algorithm for the parameterized Vertex Cover problem which computes a sketch using $\tilde{O}(nk)$ space such that in time $\tilde{O}(nk + 2^{k^2})$ it can either extract a solution of size at most $k$ for the final instance, or report that no such solution exists.

We also show a tight lower bound of $\Omega(k^2)$ for the space complexity of any (randomized) streaming algorithms for the parameterized Vertex Cover, even in the insertion-only model.

$\tilde{O}(f(k)) = O(f(k) \cdot \log^{O(1)} m)$, where $m$ is the number of edges.
1 Introduction

Many large graphs are presented in the form of a sequence of edges. This stream of edges may be a simple stream of edge arrivals, where each edge adds to the graph seen so far, or may include a mixture of arrivals and departures of edges. In either case, we want to be able to quickly answer basic optimization questions over the current state of the graph, such as finding a (maximal) matching over the current graph edges, or finding a (minimum) vertex cover, while storing only a limited amount of information, sublinear in the size of the current graph.

The semi-streaming model introduced by Feigenbaum, Kannan, McGregor, Suri and Zhang [14] is a classical streaming model in which maximal matching and vertex cover are studied. In the semi-streaming model we are interested to solve (mostly approximately) graph problems using one pass over the graph and using $O(n \text{ polylog } n)$ space. Numerous problems have been studied in this setting, such as maintaining random walks and page rank over large graphs [32].

However, in many real world applications, we often observe instances of graph problems whose solutions are small comparing to the size of input. Consider for example the problem of finding the minimum number of fire stations to cover an entire city, or other cases where we expect a small number of facilities will serve a large number of locations. In these scenarios, assuming that the number of fire stations or facilities is a small number $k$ is very practical. So, it will be interesting to solve instances of graph problems (like minimal matching and vertex cover) whose solutions are small (say, sublinear in the input size) in a streaming fashion using space which is bounded with respect to the size of their solutions, not the input size.

In this paper to solve graph problems whose solutions are small, we parameterize problems with a parameter $k$, and solve the decision problem of finding whether there exists a solution whose size is bounded by $k$. We therefore seek parameterized streaming algorithms whose space and time complexities are bounded with respect to $k$, i.e., sublinear in the size of the input.

There are several ways to formalize this question, and we give results for the most natural formalizations. The basic case is when the input consists of a sequence of edge arrivals only, for which we seek a parameterized streaming algorithm (PSA). More challenging problems arise when the input stream is more dynamic, and can contain both deletions and insertions of edges. In this case we seek a dynamic parameterized streaming algorithm (DPSA). The challenge here is that when an edge in the matching is deleted, we sometimes need substantial work to repair the solution, and have to ensure that the algorithm has enough information to do so, while keeping only a bounded amount of working space. If we are promised that at every timestamp there is a solution of cost $k$, then we seek a promised dynamic parameterized streaming algorithm (PDPSA).

1.1 Parameterized Complexity

Most interesting optimization problems on graphs are NP-hard, implying that, unless P=NP, there is no polynomial time algorithm that solves all the instances of an NP-hard problem exactly. However as noted by Garey and Johnson [19], hardness results such as NP-hardness should merely constitute the beginning of research. The traditional way to combat intractability is to design approximation algorithms or randomized algorithms which run in polynomial time. These methods have their own shortcomings: we either get an approximate solution or lose the guarantee that the output is always correct.

Parameterized complexity is essentially a two-dimensional analogue of “P vs NP”. The running time is analyzed in finer detail: instead of expressing it as a function of only the input size $n$, one or more parameters of the input instance are defined, and we investigate the effects of these parameters on the running time. The goal is to design algorithms that work efficiently if the parameters of the input instance are small, even if the size of the input is large. We refer the reader to [11][17] for more background.
A parameterization of a decision problem \( P \) is a function that assigns an integer parameter \( k \) to each instance \( I \) of \( P \). We assume that instance \( I \) of problem \( P \) has the corresponding input \( X = \{x_1, \ldots, x_m\} \) consisting of elements \( x_i \) (e.g. edges defining a graph). We denote the input size of instance \( I \) by \( |I| = m \). In what follows, we assume that \( f(k) \) and \( g(k) \) are functions of an integer parameter \( k \).

**Definition 1** (Fixed-Parameter Tractability (FPT)). A parameterized problem \( P \) is fixed-parameter tractable (FPT) if there is an algorithm that in time \( f(k) \cdot m^{O(1)} \) returns a solution for each instance \( I \) whose size fulfills a given condition corresponding to \( k \) (say, at most \( k \) or at least \( k \)) or reports that such a solution does not exist.

To illustrate this concept, we define the parameterized version of Vertex Cover as follows. A vertex cover of an undirected graph \( G = (V, E) \) is a subset \( S \) of vertices such that for every edge \( e \in E \) at least one of the endpoints (or vertices) of \( e \) is in \( S \).

**Definition 2** (Parameterized Vertex Cover (VC\((k)\))). Given an instance \( (I, k) \) where \( I \) is an undirected graph \( G = (V, E) \) (with input size \( |I| = |E| = m \) and \( |V| = n \)) and parameter \( k \in \mathbb{N} \), the goal in the parameterized Vertex Cover problem (VC\((k)\) for short) is to develop an algorithm that in time \( f(k) \cdot m^{O(1)} \) either returns a vertex cover of size at most \( k \) for \( G \), or reports that \( G \) does not have any vertex cover of size at most \( k \).

A simple branching method gives a \( 2^k \cdot m^{O(1)} \) algorithm for VC\((k)\): choose any edge and branch on choosing either end-point of the edge into the solution. The current fastest FPT algorithm for VC\((k)\) is due to Chen et al. [9] and runs in time \( 1.2738^k \cdot m^{O(1)} \).

One of the techniques used to obtain FPT algorithms is kernelization. In fact, it is known that a problem is FPT if and only if it has a kernel [17]. Kernelization has been used to design efficient algorithms by using polynomial-time preprocessing to replace the input by another equivalent input of smaller size. More formally, we have:

**Definition 3** (Kernelization). For a parameterized problem \( P \), kernelization is a polynomial-time transformation that maps an instance \( (I, k) \) of \( P \) to an instance \( (I', k') \) such that

- \( (I, k) \) is a yes-instance if and only if \( (I', k') \) is a yes-instance;
- \( k' \leq g(k) \) for some computable function \( g \);
- the size of \( I' \) is bounded by some computable function \( f \) of \( k \), i.e., \( |I'| \leq f(k) \).

The output \( (I', k') \) of a kernelization algorithm is called a kernel.

In Section 3.1 we review the kernelization algorithm of Buss and Goldsmith [6] for the parameterized Vertex Cover problem which relies on finding a maximal matching of a graph \( G = (V, E) \). This kernel gives a graph with \( O(k^2) \) vertices and \( O(k^2) \) edges. Another kernelization algorithm given in [17] exploits the half-integrality property of LP-relaxation for vertex cover due to Nemhauser and Trotter, and produces a graph with at most \( 2k \) vertices.

### 1.2 Parameterized Streaming Algorithms: Our Results

In order to state our results for parameterized streaming we first define the notion of a sketch in a very general form.

**Definition 4** (Sketch [3, 15, 20]). A sketch is a sublinear-space data structure that supports a fixed set of queries and updates.
**Insertion-Only Streaming**. Let \( P \) be a problem parameterized by \( k \in \mathbb{N} \). Let \( I \) be an instance of \( P \) that has the input \( X = \{x_1, \ldots, x_i, \ldots, x_m\} \). Let \( S \) be a stream of \( \text{INSERT}(x_i) \) (i.e., the insertion of an element \( x_i \)) operations of underlying instance \((I, k)\). In particular, stream \( S \) is a permutation \( X' = \{x'_1, \ldots, x'_i, \ldots, x'_m\} \) for \( x'_i \in X \) of an input \( X \). Here we denote the time when an input \( x'_i \) is inserted by \( \text{time } i \). At time \( i \), the input which corresponds to instance \( I \) is \( X'_i = \{x'_1, \ldots, x'_i\} \).

**Definition 5**. (Parameterized Streaming Algorithm (PSA)) Given stream \( S \), let \( A \) be an algorithm that computes a sketch for problem \( P \) using \( \tilde{O}(f(k)) \)-space and with one pass over stream \( S \). Suppose at a time \( i \), algorithm \( A \) in time \( \tilde{O}(g(k)) \) extracts, from the sketch, a solution for input \( X'_i \) (of instance \( I \)) whose size fulfills the condition corresponding to \( k \) or reports that such a solution does not exist. Then we say \( A \) is a \((f(k), g(k))\)-PSA.

For many problems, whether or not there is a solution of size at most \( k \) is monotonic under edge additions, and so if at time \( i \), algorithm \( A \) reports that a solution for input \( X'_i \) does not exist, then there is also no solution for any input \( X'_j \) of instance \( I \) at all times \( i > j \). Consequently, we can terminate the algorithm \( A \).

We state our result on the parameterized streaming algorithm for Vertex Cover and prove it in Section 3.

**Theorem 6**. Let \( S \) be a stream of insertions of edges of an underlying graph \( G \). Then there exists a deterministic \((k^2, 2^{2k^2})\)-PSA for \( \text{VC}(k) \) problem.

The best known kernel size for the \( \text{VC}(k) \) problem is \( O(k^2) \) edges [6]. In fact, Dell and van Melkebeek [10] showed that it is not possible to get a kernel for the \( \text{VC}(k) \) problem with \( O(k^{2-\epsilon}) \) edges for any \( \epsilon > 0 \), under some assumptions from classical complexity. Interestingly, the space complexity of our PSA of Theorem matches this best known kernel size. In Section 3, we show that the space complexity of above PSA is optimal even if we use randomization. More precisely, we prove the following result.

**Theorem 7**. Any (randomized) PSA for the \( \text{VC}(k) \) problem requires \( \Omega(k^2) \) space.

**Dynamic Streaming**. We define dynamic parameterized stream as a generalization of dynamic graph stream introduced by Ahn, Guha and McGregor [1].

**Definition 8** (Dynamic Parameterized Stream). Let \( P \) be a problem parameterized by \( k \in \mathbb{N} \). Let \( I \) be an instance of \( P \) that has an input \( X = \{x_1, \ldots, x_i, \ldots, x_m\} \) with input size \( |I| = m \). We say stream \( S \) is a dynamic parameterized stream if \( S \) is a stream of \( \text{INSERT}(x_i) \) (i.e., the insertion of an element \( x_i \)) and \( \text{DELETE}(x_i) \) (i.e., the deletion of an element \( x_i \)) operations applying to the underlying instance \((I, k)\) of \( P \).

Now stream \( S \) is not simply a permutation \( X' = \{x'_1, \ldots, x'_i, \ldots, x'_m\} \) for \( x'_i \in X \) of an input \( X \), but rather a sequence of transactions that collectively define a graph. We assume the size of stream \( S \) is \( |S| \leq m^c \) for a constant \( c \) which means \( \log |S| \leq c \log m \) or asymptotically, \( O(\log |S|) = O(\log m) \). We denote the time which corresponds to the \( i \)-th update operation of \( S \) by \( \text{time } i \). The \( i \)-th update operation can be \( \text{INSERT}(x'_i) \) or \( \text{DELETE}(x'_i) \) for \( x'_i \in X \) (note that we can perform \( \text{DELETE}(x'_i) \) only if \( x'_i \) is present at time \( i - 1 \)). At time \( i \), the input of instance \( I \) is a subset \( X'_i \subseteq X \) of inputs which are, up to time \( i \), inserted but not deleted.

We next define a promised streaming model as follows. Suppose we know for sure that at every time \( i \) of a dynamic parameterized stream \( S \), the size of the vertex cover of underlying graph \( G(V, E) \) (where \( E \) is the set of edges that are inserted up to time \( i \) but not deleted) is at most \( k \). We show that within the framework of the promised streaming model we are able to develop a dynamic parameterized streaming algorithm whose space usage matches the lower bound of Theorem up to \( O(1) \) factor.

We formulate a dynamic parameterized streaming algorithm within the framework of the promised streaming model as follows.
Definition 9. (Promised Dynamic Parameterized Streaming Algorithm (PDPSA)) Let \( S \) be a promised dynamic parameterized stream, i.e., we are promised that at every time \( i \), there is a solution for input \( X'_i \) whose size fulfills the condition corresponding to \( k \). Let \( A \) be an algorithm that computes a sketch for problem \( P \) using \( \tilde{O}(f(k)) \)-space in one pass over stream \( S \). Suppose at the end of stream \( S \), i.e., time \( |S| \), algorithm \( A \) in time \( \tilde{O}(g(k)) \) extracts, from the sketch, a solution for input \( X'_i \) (of instance \( I \)) whose size fulfills the condition corresponding to \( k \). We say \( A \) is an \((f(k), g(k))\)-PDPSA.

Next, using the well-known connection (see, for example, Chapter 9 of [17]) between maximal matching and kernelization algorithms for parameterized Vertex Cover, we show that kernels for matching can be implemented in data streams in small space, and this in turn gives a PDPSA for VC\((k)\) problem. We summarize this main result in the following theorem and we develop it in Section 4.

Theorem 10. Suppose at every timestep the size of the vertex cover of underlying graph \( G(V, E) \) is at most \( k \). There exists a \((k^2, 2^{2k^2})\)-PDPSA for VC\((k)\) with probability \( \geq 1 - \delta/n^c \), where \( \delta < 1 \) and \( c \) is a constant.

Our algorithm takes the novel approach of combining linear sketching with sequential operations that depend on the current state of the graph. Prior work in sketching has instead only performed updates of sketches for each stream update, and postponed inspecting them until the end of the stream.

As a byproduct of this main theorem we have the following corollary.

Corollary 11. Assume we are promised that a maximal matching of underlying graph \( G(V, E) \) at every time \( i \) of dynamic parameterized stream \( S \) is of size at most \( k \) for \( k \in \mathbb{N} \). Then, there exists a dynamic algorithm that maintains a maximal matching of graph \( G(V, E) \) using \( \tilde{O}(k^2) \) space. The update time (i.e., the time to maintain the sketch) and query time (i.e., the time to maintain a maximal matching using the sketch) of this algorithm are worst-case \( \tilde{O}(k) \). For \( k = \tilde{O}(\sqrt{n}) \), this gives a dynamic algorithm for maximal matching whose space, worst-case update and query times are \( \tilde{O}(n) \), \( \tilde{O}(\sqrt{n}) \) and \( \tilde{O}(\sqrt{n}) \), respectively.

Finally, we formulate a dynamic parameterized streaming algorithm without any promise as follows.

Definition 12. (Dynamic Parameterized Streaming Algorithm (DPSA)) Let \( S \) be a dynamic parameterized stream \( S \). Let \( A \) be an algorithm that computes a sketch for problem \( P \) using \( \tilde{o}(m) \cdot f(k) \)-space and with one pass over stream \( S \). Suppose at the end of stream \( S \), i.e., time \( |S| \), algorithm \( A \) in time \( \tilde{o}(m) \cdot g(k) \) extracts, from the sketch, a solution for input \( X'_i \) whose size fulfills the condition corresponding to \( k \) or reports that such a solution does not exist. We say \( A \) is an \((\tilde{o}(m) \cdot f(k), \tilde{o}(m) \cdot g(k))\)-DPSA.

We state our result on the DPSA (without any promise) for Vertex Cover and prove it in Section 5.

Theorem 13. Let \( S \) be a dynamic parameterized stream of insertions and deletions of edges of an underlying graph \( G \). There exists a randomized \((\min(m, nk), \min(m, nk) + 2^{2k^2})\)-DPSA for VC\((k)\) problem.

For graphs which are not sparse (i.e., \( m > O(nk) \)) the algorithm of Theorem 13 gives \((\tilde{o}(m) \cdot f(k), \tilde{o}(m) \cdot g(k))\)-DPSA for VC\((k)\). The space usage of PDPSA of Theorem 10 matches the lower bound of Theorem 7. On the other hand, there is a gap between space bound \( \tilde{O}(nk) \) of DPSA of Theorem 13 and lower bound \( \Omega(\sqrt{n}) \) of Theorem 7. We conjecture that the lower bound for the space usage of any (randomized) DPSA for VC\((k)\) problem is indeed \( \Omega(nk) \).

1.3 Related Work

The question of finding maximal and maximum cardinality matchings has been heavily studied in the model of (insert-only) graph streams. A greedy algorithm trivially obtains a maximal matching (simply store every edge that links two currently unmatched nodes); this can also be shown to be a 0.5-approximation to the
maximum cardinality matching \cite{16}. By taking multiple passes over the input streams, this can be improved to a $1 - \epsilon$ approximation, by finding augmenting paths with successive passes \cite{25} \cite{26}.

Subsequent work has extended to the case of weighted edges (when a maximum weight matching is sought), and reducing the number of passes to provide a guaranteed approximation \cite{13} \cite{12}. While approximating the size of the vertex cover has been studied in other sublinear models, such as sampling \cite{31} \cite{30}, we are not aware of prior work that has addressed the question of finding a vertex cover over a graph stream. Likewise, parameterized complexity has not been explicitly studied in the streaming model, so we initiate it here.

The model of dynamic graph streams has recently received much attention, due to breakthroughs by Ahn, Guha and McGregor \cite{1} \cite{2}. Over two papers, they showed the first results for a number of graph problems over dynamic streams, including determining connected components, testing bipartiteness, minimum spanning tree weight and building a sparsifier. They also gave multipass algorithms for maximum weight matchings and spanner constructions. This has provoked much interest into what can be computed over dynamic graph streams.

**Outline.** Section \ref{sec:preliminaries} provides background on techniques for kernelization of graph problems, and on streaming algorithms for building a sketch to recover a compact set. Our results on PSA and DPSA are stated in Section \ref{sec:psa} and Section \ref{sec:dpsa}, respectively. Section \ref{sec:upperbounds} is the most involved, as it addresses the most difficult dynamic case in the promised model.

## 2 Preliminaries

In this section, we present the definitions of streaming model and the graph sketching that we use.

**Streaming Model.** Let $S$ be a stream of insertions (or similarly, insertions and deletions) of edges of an underlying graph $G(V, E)$. We assume that vertex set $V$ is fixed and given, and the size of $V$ is $|V| = n$. We assume that the size of stream $S$ is $|S| \leq n^c$ for some large enough constant $c$ so that we may assume that $O(\log |S|) = O(\log n)$. Here $[x] = \{1, 2, 3, \cdots, x\}$ when $x \in \mathbb{N}$. Throughout the paper we denote a failure probabilities by $\delta$, and approximation parameters by $\epsilon$.

We assume that there is a unique numbering for the vertices in $V$ so that we can treat $v \in V$ as a unique number $v$ for $1 \leq v \leq n = |V|$. We denote an undirected edge in $E$ with two endpoints $u, v \in V$ by $(u, v)$. The graph $G$ can have at most $\binom{n}{2} = n(n-1)/2$ edges. Thus, each edge can also be thought of as referring to a unique number between $1$ and $\binom{n}{2}$.

At the start of stream $S$, edge set $E$ is an empty set. We assume in the course of stream $S$, the maximum size of $E$ is a number $m$, i.e., $m' = |E| \leq m$. Counter $m'$ stores the current number of edges of stream $S$, i.e., after every insertion we increment $m'$ by one and after every deletion we decrement $m'$ by one.

Let $M$ be a maximal matching that we maintain for stream $S$. Edges in $M$ are called matched edges; the other edges are free. If $uv$ is a matched edge, then $u$ is the mate of $v$ and $v$ is the mate of $u$. Let $V_M$ be the vertices of $M$ and $\overline{V}_M = V \setminus V_M$. A vertex $v$ which is in $V_M$ is called a matched vertex, otherwise, i.e., if $v \in \overline{V}_M$, $v$ is called an exposed vertex.

The neighborhood of a vertex $u \in V$ is defined as $N_u = \{v \in V : uv \in E\}$. Hence the degree of a vertex $u \in V$ is $d_u = |\{uv \in E\}| = |N_u|$. We split the neighborhood of $u$ into the set of matched neighbors of $u$, $N'_u \cap V_M$, and the set of exposed neighbors of $u$, i.e., $N_u \setminus V_M$.

**Oblivious Adversarial Model.** We work in the oblivious adversarial model as is common for analysis of randomized data structures such as universal hashing \cite{8}. This model has been used in a series of papers on dynamic maximal matching and dynamic connectivity problems; see for example \cite{29} \cite{5} \cite{22} \cite{28}. The model allows the adversary to know all the edges in the graph $G(V, E)$ and their arrival order, as well as the algorithm to be used. However, the adversary is not aware of the random bits used by the algorithm,
and so cannot choose updates adaptively in response to the randomly guided choices of the algorithm. This effectively means that we can assume that the adversary prepares the full input (inserts and deletes) before the algorithm runs.

**k-Sparse Recovery Sketch and Graph Sketching.** We first define an $\ell_0$-Sampler as follows.

**Definition 14 ($\ell_0$-Sampler [18, 27]).** Let $0 < \delta < 1$ be a parameter. Let $S = (a_1, t_1), \cdots, (a_i, t_i), \cdots$ be a stream of updates of an underlying vector $x \in \mathbb{R}^n$ where $a_i \in [n]$ and $t_i \in \mathbb{R}$. The $i$-th update $(a_i, t_i)$ updates the $a_i$-th element of $x$ using $x[a_i] = x[a_i] + t_i$. A $\ell_0$-sampler algorithm for $x \neq 0$ returns FAIL with probability at most $\delta$. Else, with probability $1 - \delta$, it returns an element $j \in [n]$ such that the probability that $j$-th element is returned is $\Pr[j] = |x[j]|^0 \ell_0(x)$.

Here, $\ell_0(x) = (\sum_{i \in [n]} |x[i]|^0)$ is the (so-called) “0-norm” of $x$ that counts the number of non-zero entries.

**Lemma 15 ([21]).** Let $0 < \delta < 1$ be a parameter. There exists a linear sketch-based algorithm for $\ell_0$-sampling using $O(\log^2 n \log \delta^{-1})$ bits of space.

The concepts behind sketches for $\ell_0$-sampling can be generalized to draw $k$ distinct elements from the support set of $x$:

**Definition 16 (k-sample recovery).** A $k$-sample recovery algorithm recovers $\min(k, \|x\|_0)$ elements from $x$ such that sampled index $i$ has $x_i \neq 0$ and is sampled uniformly.

Constructions of $k$-sample recovery mechanisms are known which require space $\tilde{O}(k)$ and fail only with probability polynomially small in $n$ [4]. We apply this algorithm to the neighborhood of vertices: for each node $v$, we can maintain an instance of the $k$-sample recovery sketch (or algorithm) to the vector corresponding to the row of the adjacency matrix for $v$. Note that as edges are inserted or deleted, we can propagate these to the appropriate $k$-sample recovery algorithms, without needing knowledge of the full neighborhood of nodes.

Specifically, let $a_1, \cdots, a_n$ be the rows of the adjacency matrix of $G$, $A_G$, where $a_v$ encodes the neighborhood of a vertex $v \in V$. We define the sketch of $A_G$ as follows. Let $S$ be a stream of insertions and deletions of edges to an underlying graph $G = (V, E)$. We sketch each row $a_u$ of $A_G$ using the sketching matrix of Lemma [15]. Let us denote this sketch by $S_u$. Since sketch $S$ is linear, the following operations can be done in the sketch space.

- **QUERY($S_u$)**: This operation queries sketch $S_u$ to find a uniformly random neighbor of vertex $u$. Since $S_u$ is a $k$-sample recovery sketch, we can query up to $k$ uniformly random neighbors of vertex $u$.

- **UPDATE($S_u, \pm(u, v)$)**: This operation updates the sketch of a vertex $u$. In particular, operation UPDATE($S_u, (u, v)$) means that edge $(u, v)$ is added to sketch $S_u$. And, operation UPDATE($S_u, -(u, v)$) means that edge $(u, v)$ is deleted from sketch $S_u$.

### 3 Parameterized Streaming Algorithm (PSA) for VC($k$)

In this section, we give a $(k^2, 2^{2k^2})$-PSA for VC($k$) along with a matching $\Omega(k^2)$ lower bound for the space complexity of VC($k$). First, we review the kernelization algorithm of Buss and Goldsmith [6] since we use it in our PSA for VC($k$).
3.1 Kernel for VC(k)

Let \((G, k)\) be the original instance of the problem which is initialized by graph \(G = (V, E)\) and parameter \(k\). Let \(d_v\) denote the degree of \(v\) in \(G\). While one of the following rules can be applied, we follow it.

1. There exists a vertex \(v \in G\) with \(d_v > k\): Observe that if we do not include \(v\) in the vertex cover, then we must include all of \(N_v\). Since \(|N_v| = d_v > k\), we must include \(v\) in our vertex cover for now. Update \(G \leftarrow G \setminus \{v\}\) and \(k \leftarrow k - 1\).

2. There is an isolated vertex \(v \in G\): Remove \(v\) from \(G\), since \(v\) cannot cover any edge.

If neither of above rules can be applied, then we look at the number of edges of \(G\). Note that the maximum degree of \(G\) is now \(\leq k\). Hence, if \(G\) has a vertex cover of size \(\leq k\), then the maximum number of edges in \(G\) is \(k^2\). If \(|E| > k^2\), then we can safely answer NO. Otherwise we now have a kernel graph \(G = (V, E)\) such that \(|E| \leq k^2\). Since \(G\) does not have any isolated vertex, we have \(|V| \leq 2|E| \leq 2k^2\). Observe that we obtain the kernel graph \(G\) in polynomial time.

Now we show how to obtain an FPT algorithm for Parameterized Vertex Cover using the above kernelization: Enumerate all vertex subsets of \(G\) of size \(k\), and checks whether any of them forms a vertex cover. The number of such subsets is \(\binom{2k^2}{k} = 2^{O(k^3)}\), and checking whether a given subset is a vertex cover can be done in polynomial time. We answer YES if any of the subsets of size \(k\) forms a vertex cover, and NO otherwise. After obtaining the kernel graph in polynomial time, the running time of this algorithm is \(2^{O(k^3)} \cdot n^{O(1)}\).

3.2 \((k^2, 2k^2)\)-PSA for VC(k)

We now prove Theorem 6, which is restated below:

Theorem 6 Let \(S\) be a stream of insertions of edges of an underlying graph \(G\). Then there exists a deterministic \((k^2, 2k^2)\)-PSA for VC(\(k\)) problem.

Proof. The proof is divided into three parts: first we describe the algorithm, analyze its complexity and then show its correctness.

Algorithm. Let \(S\) be a stream of insertions of edges of an underlying graph \(G(V, E)\). We maintain a maximal matching \(M\) of stream \(S\) in a greedy fashion. Let \(V_M\) be the vertices of matching \(M\). For every matched vertex \(v\), we also store up to \(k\) edges incident on \(v\) in a set \(E_M\). If at a timestamp \(i\) of stream \(S\) we observe that \(|M| > k\), we report that the size of any vertex cover of \(G = (V, E)\) is more than \(k\) and quit. At the end of stream \(S\), we run the kernelization algorithm of Section 3.1 on instance \((G_M = (V_M, E_M), k)\).

Complexity of the Algorithm. We observe that the space complexity of the algorithm is \(O(k^2)\). In fact, for each vertex \(v \in V_M\) assuming \(|M| \leq k\) we keep at most \(k\) edges, thus we need space of at most \(2k \cdot k = 2k^2\). If \(|M| > k\), as soon as the size of the matching \(M\) goes beyond \(k\) we quit the algorithm and so in this case we also use space of at most \(2k \cdot k = 2k^2\). The query time of this algorithm is dominated by the time to extract the vertex cover of \(G_M\) (and also of \(G\)) using the brute-force search algorithm (if one exists), which is \(2^{O(2k^2)}\).

Correctness. We argue that

1. if the kernelization algorithm succeeds on instance \((G_M = (V_M, E_M), k)\) and finds a vertex cover of size at most \(k\) for \(G_M\), then that vertex cover is also a vertex cover of size at most \(k\) for \(G\).
(2) On the other hand, if the kernelization algorithm reports that instance \((G_M = (V_M, E_M), k)\) does not have a vertex cover of size at most \(k\), then instance \((G = (V, E), k)\) does not have a vertex cover of size at most \(k\).

First, note that trivially, any matching provides a lower bound on the size of the vertex cover, and hence we are correct to reject if \(|M| > k\).

Otherwise, i.e., if \(|M| \leq k\), we write \(d_v\) and \(d'_v\) for the degree of \(v\) in \(G\) and \(G_M\), respectively. We follow rules of the kernelization algorithm on \(G\) and \(G_M\) in lockstep. Observe that since every edge \(e \in E\) is incident on at least one matched vertex \(v \in V_M\), when an edge \((u, v) \in E\) is not stored in \(E_M\) it is in one of the following cases.

\begin{enumerate}
\item \(u \in V_M\) and \(v \in V_M\): Then, we must have \(d'_v > k\) and \(d'_u > k\) which means that \(d_u > k\) and \(d_v > k\).
\item Only \(u \in V_M\): Then, we must have \(d'_u > k\) which means that \(d_u > k\).
\item Only \(v \in V_M\): Then, we must have \(d'_v > k\) which means that \(d_v > k\).
\end{enumerate}

Now, let us consider a set \(X = \{v_k, v_{k-1}, \ldots, v_r\}\) (for \(r \geq 0\)) of vertices that Rule (1) of the kernelization algorithm for \(G_M\) removes. According to Rule (1), for a vertex \(v_k' \in X\) (for \(k \geq k' \geq r\)) with \(d'_{v_k'} > k'\), we remove \(v_k\) and all edges incident on \(v_k\) from \(G_M\) and decrease \(k'\) by one. Note that \(d'_{v_k'} > k'\) iff \(d_{v_k'} > k'\). This is due to the fact that, before we remove vertex \(v_k\) from \(G_M\), we have removed only those neighbors of \(v_k\) that are matched and the number of such vertices is less than \(k - k'\). Thus, Rule (1) of the kernelization algorithm can be applied on \(G\) and we remove \(v_k\) and all edges incident on \(v_k\) from \(G\) and decrease \(k'\) by one.

Next, we consider Rule (2). Assume in one step of the kernelization algorithm for \(G_M\), we have an isolated vertex \(v \in G_M\). Observe that those neighbors of \(v\) that we have removed using Rule (1) (before vertex \(v\) becomes isolated) are all matched vertices and the number of such vertices is less than \(k\). Moreover, \(v\) never had any neighbor in \(V \backslash V_M\) otherwise, \(v\) is not isolated. Thus, if \(v\) has a neighbor \(u\) in the remaining vertices of \(V_M\), edge \((u, v)\) must be in \(E_M\) as we store up to \(k\) edges incident on \(v\) in set \(E_M\) which means \(v\) is not isolated in \(G_M\) and that is in contradiction to our assumption that \(v\) is isolated in \(G_M\). Since we run the kernelization algorithm on \(G_M\) and on \(G\) for the vertices in set \(X\), the same thing happens for \(G\), i.e., \(v\) in \(G\) is also isolated. So, using Rule (2), \(v\) is removed from \(G_M\) iff \(v\) is removed from \(G\).

Now assume neither Rule (1) nor Rule (2) can be applied for \(G_M\), but the number of edges in \(E_M\) is more than \(k^2\). The same thing must happen for \(E\). Therefore, \(G_M\) and \(G\) do not have a vertex cover of size at most \(k\).

If none of the above rules can be applied for \(G_M\), we have a kernel \((G_M, k')\) such that \(|V_M| \leq 2k\) and \(|E_M| \leq k^2 \leq k^2\). Now observe that after removal of all vertices of \(X\) and their incident edges from \(G\), for every remaining vertex \(v\) in \(G_M\), \(d_v \leq k'\); otherwise \(d_v > k'\) and \(d'_v > k'\); so we can apply Rule (1) which is in contradiction to our assumption that none of the above rules can be applied for \(G_M\). Therefore, kernel \((G_M, k')\) is also a kernel for \((G, k')\) and this proves the correctness of our algorithm.

\[\square\]

### 3.3 \(\Omega(k^2)\) Lower Bound for \(VC(k)\)

Next, we prove Theorem 7 which is restated below:

**Theorem 7.** Any (randomized) PSA for the \(VC(k)\) problem requires \(\Omega(k^2)\) space.

**Proof.** We will reduce from the INDEX problem in communication complexity:

**INDEX**

- **Input:** Alice has a string \(X \in \{0, 1\}^n\) given by \(x_1x_2 \ldots x_n\). Bob has an index \(i \in [n]\)
- **Question:** Bob wants to find \(x_i\), i.e., the \(i^{th}\) bit of \(X\).
It is well-known that there is a lower bound of $\Omega(n)$ bits in the one-way randomized communication model for Bob to compute $x_i$. We assume an instance of the index problem where $n$ is a perfect square, and let $k = \sqrt{n}$. Fix a canonical mapping from $[n] \rightarrow [k] \times [k]$. Consequently we can interpret the bit string as an adjacency matrix for a bipartite graph with $k$ vertices on each side.

From the instance of INDEX, we construct an instance $G_X$ of Vertex Cover. Assume that Alice has an algorithm which solves the VC($k$) problem using $f(k)$ bits. For each $i \in [k]$, we have vertices, $v_i, v'_i, v''_i$, and $w_i, w'_i, w''_i$. First, we insert the edges corresponding to the edge interpretation of $X$ between nodes $v_i$ and $w_j$: for each $i, j \in [k]$, Alice adds the edge $(v_i, w_j)$ if the corresponding entry in $X$ is 1. Alice then sends the memory contents of her algorithm to Bob, using $f(k)$ bits.

Bob has the index $i \in [n]$, which he interprets as $(I, J)$ under the same canonical remapping to $[k] \times [k]$. He receives the memory contents of the algorithm, and proceeds to add edges to the instance of vertex cover. For each $i \in [k], i \neq I$, Bob adds the edges $(v_i, v'_i)$ and $(v_i, v''_i)$. Similarly, for each $j \in [k], j \neq J$, Bob adds the edges $(w_j, w'_j)$ and $(w_j, w''_j)$.

The next lemma shows that finding the minimum vertex cover of $G_X$ allows us to solve the corresponding instance of INDEX.

**Lemma 17.** The minimum size of a vertex cover of $G_X$ is $2k - 1$ if and only if $x_i = 1$.

**Proof.** Suppose $x_i = 0$. Then it is easy to check that the set $\{v_i : i \in [k], i \neq I\} \cup \{w_j : j \in [k], j \neq J\}$ forms a vertex cover of size $2k - 2$ for $G_X$.

Now suppose $x_i = 1$, and let $Y$ be a minimum vertex cover for $G_X$. For any $i \in [k], i \neq I$ the vertices $v'_i, v''_i$ have degree one in $G_X$. Hence, without loss of generality, we can assume that $v_i \in Y$. Similarly, $w_j \in Y$ for each $j \in [k], j \neq J$. This covers all edges except $(v_i, w_j)$. To cover this we need to pick one of $v_i$ or $v_j$, which shows that $|Y| = 2k - 1$.

Thus, by checking whether the output of $A$ on the instance $G_X$ of VC($k$) is $2k - 1$ or $2k - 2$, Bob can determine the index $x_i$. The total communication between Alice and Bob was $O(f(k))$ bits, and hence we can solve the INDEX problem in $f(k)$ bits. Recall that the lower bound for the INDEX problem is $\Omega(n) = \Omega(k^2)$, and hence we have $f(k) = \Omega(k^2)$.

**Corollary 18.** Let $1 > \epsilon > 0$. Any (randomized) PSA that approximates VC($k$) within a relative error of $\epsilon$ requires $\Omega(\frac{1}{\epsilon})$ space.

**Proof.** Choose $\epsilon = \frac{1}{2k}$. Theorem 17 shows that the relative error is at most $\frac{1}{2k}$, which is less than $\epsilon$. Hence finding an approximation within $\epsilon$ relative error amounts to finding the exact value of the vertex cover. The lower bound of $\Omega(k^2)$ from Theorem 17 translates to $\Omega(\frac{1}{\epsilon^2})$ here.

## 4 Promised Dynamic Parameterized Streaming Algorithm (PDPSA) for VC($k$)

In this section we prove Theorem 10 which is restated here. We let $c$ be a constant so that for the length of stream $S$ we have $|S| \leq n^c$.

**Theorem 10.** Assume that at every timestep the size of the vertex cover of underlying graph $G(V, E)$ is at most $k$. There exists a $(k^2, 2^{2k^2})$-PDPSA for VC($k$) problem with probability at least $1 - \frac{\delta}{n^c}$, where $\delta < 1$ and $c$ is a constant.
4.1 Outline

We develop a streaming algorithm that maintains a maximal matching of underlying graph \( G(V, E) \) in a streaming fashion. At the end of stream \( S \) we run the kernelization algorithm of Section 3.1 on the maintained maximal matching. Our data structure to maintain a maximal matching \( M \) of underlying graph \( G \) is chosen to be \( \tilde{O}(k) \). Insertions of new edges are relatively easy to handle: we update the matching with the edge if we can, and update the sketches if the new edge is incident on matched nodes. The difficulty arises with deletions of edges: we must try to “patch up” the matching, so that it remains maximal, using only the stored information, which is constrained to be \( O(k^2) \). The intuition behind our algorithm is that, given the promise, there cannot be more than \( k \) matched nodes at any time. Therefore, keeping \( \tilde{O}(k) \) information about the neighborhood of each matched node can be sufficient to identify any adjacent unmatched nodes with which it can be paired if it becomes unmatched. However, this intuition requires significant care and case-analysis to put into practice. The reason is that we need some extra book-keeping to record where information is stored, since nodes are entering and leaving the matching, and we do not necessarily have access to the full neighborhood of a node when it is admitted to the matching. Nevertheless, we show that additional book-keeping information of size \( O(k^2) \) is sufficient for our purposes, allowing us to meet the \( O(k^2) \) space bound.

This book-keeping comes in the form of another data structure \( T \), that stores a set of edges \((u, v)\) such that both endpoints are matched (not necessarily to each other), and \((u, v)\) has been inserted into sketches \( S_u \) and \( S_v \), but not deleted from them. The size of \( T \) is clearly \( O(k^2) \). To implement \( T \), we can adopt any fast dictionary data structure (AVL-tree, red-black tree, or hash-tables).

The update at a time \( t \) is either the insertion or the deletion of an edge \((u, v)\) for \( 1 \leq t \leq |S| \) where \( |S| \leq n^2 \) is the length of stream \( S \). We continue our outline of the algorithm by describing the behavior in each case informally, with the formal details spelled out in subsequent sections.

**Insertion of an Edge** \((u, v)\) **at Time** \( t \). When the update at time \( t \) is insertion of an edge \((u, v)\) two cases can occur. The first case is if at least one of \( u \) and \( v \) is matched, we insert edge \((u, v)\) to the sketches of those vertices (from \( u \) and \( v \)) which are matched. If both \( u \) and \( v \) are matched, we also insert edge \((u, v)\) to \( T \).

The second case occurs if both vertices \( u \) and \( v \) are exposed. We add edge \((u, v)\) to the current matching and to \( T \), and initialize sketches \( S_u \) and \( S_v \) by insertion of edge \((u, v)\) to \( S_u \) and \( S_v \). However, we also need to perform some additional book-keeping updates to ensure that the information is up to date. Fix one of the nodes \( u \). There can be matched vertices, say \( w \in V_M \), which are neighbors of \( u \). If previously an edge \((w, u)\) arrived while \( u \) was not in the matching, then we inserted \((w, u)\) to sketch \( S_w \), but \((w, u)\) was not inserted to sketch \( S_u \) as \( u \) was an exposed vertex at that time. If at some subsequent point \( w \) becomes an exposed vertex and the matching edge \((u, v)\) is deleted then vertex \( u \) must have the option of choosing an unexposed vertex \( w \) to be rematched. For that, we need to ensure that some information about the edge \((w, u)\) is accessible to the algorithm.

A first attempt to address this is to try interrogating each sketch \( S_w \) for all edges incident on \( u \), say when \( u \) is first added to the matching. However, this may not work while respecting the space bounds: \( w \) may have a large number of neighbors, much larger than the limit \( x \). In this case, we can only use \( S_w \) to recover a sample of the neighbors of \( w \), and \( u \) may not be among them.

To solve this problem we must wait until \( w \) has low enough degree that we can retrieve its complete neighborhood from \( S_w \). At this point, we can use these recovered edges to update the sketches of other matched nodes. We use the structure \( T \) to track information about edges on matched vertices that are already represented in sketches, to avoid duplicate representations of an edge. This is handled during the deletion of an edge, since this is the only event that can cause the degree of a node \( w \) to drop.
Deletion of an Edge \((u,v)\) at Time \(t\). When the update at time \(t\) is deletion of an edge \((u,v)\), we have three cases to consider. The first case is if only one of vertices \(u\) and \(v\) is matched, we delete edge \((u,v)\) from the sketch of that matched vertex.

The second case is if both \(u\) and \(v\) are matched vertices, but \((u,v)\) \(\notin M\). We want to delete edge \((u,v)\) from sketches \(S_u\) and \(S_v\), but \((u,v)\) might not be represented in both these sketches. We need to find out if \((u,v)\) has been inserted to \(S_u\) and \(S_v\), or only to one of them. This can be found from \(T\). If \((u,v) \in T\), edge \((u,v)\) has been inserted to both \(S_u\) and \(S_v\). So, we delete \((u,v)\) from both sketches safely. Otherwise, i.e., if \((u,v) \notin T\), \((u,v)\) has been inserted to the sketch of only one of \(u\) and \(v\). Assume that this is \(u\). To discover this we define \textit{timestamps} for matched vertices. The timestamp \(t_i\) of a matched vertex \(u\) is the (most recent) time when \(u\) was matched. We show that edge \((u,v)\) is only in sketch \(S_u\) (not \(S_v\)) if and only if \((u,v) \notin T\) and \(t_u < t_v\). Therefore, if \(t_u < t_v\), we delete \((u,v)\) from sketch \(S_u\). Otherwise, i.e., if \(t_v < t_u\), we delete \((u,v)\) from sketch \(S_v\). Observe that if \(t_u = t_v\), we have inserted \((u,v)\) to \(S_u\) and \(S_v\) as well as \(T\).

The third case is when \((u,v) \in M\). We delete edge \((u,v)\) from sketches \(S_u\) and \(S_v\) as well as matching \(M\) and \(T\). To maintain the maximality of matching \(M\) we need to see whether we can rematch \(u\) and \(v\). Let us consider \(u\) (the case for \(v\) is identical). If \(u\) has high degree, we sample edges \((u,z)\) from sketch \(S_u\). Given the size of the sketch, we argue that there is high probability of finding an edge to rematch \(u\). Meanwhile, if \(u\) is has low degree, then we can recover its full neighborhood, and test whether any of these can match \(u\). Otherwise, \(u\) is an exposed vertex, and its sketch is deleted. We also remove all edges incident on \(u\) from \(T\).

4.2 Notations, Data Structures and Invariants

We now describe and prove the properties of this process in full. We begin with notations, data structures and invariants.

Timestamp of a Vertex and an Edge. We define \textit{time} \(t\) corresponding to the \(t\)-th update operation (insert or delete of an edge) in stream \(S\). We define the \textit{timestamp} of a matched vertex as follows. Let \(u\) be a matched vertex at time \(t\). Let \(t' \leq t\) be the greatest time such that \(u\) was unmatched before time \(t'\) and is matched in the interval \([t',t]\). Then we say the timestamp \(t_u\) of vertex \(u\) is \(t'\) and we set \(t_u = t'\). If at time \(t\), vertex \(u\) is exposed we define \(t_u = \infty\), i.e. a value larger than any timestamp.

We define the \textit{timestamp of an edge} as follows. Let \(E_t\) denote the set of edges present at time \(t\), i.e. which have been inserted without a corresponding deletion. Let \(t' \leq t\) be the last time in which the edge \((u,v) \in E_t\) is inserted but not deleted in the interval \([t',t]\). Then we say the timestamp \(t_{(u,v)}\) of edge \((u,v)\) is \(t'\) and we set \(t_{(u,v)} = t'\). If at timestamp \(t\), edge \((u,v)\) is deleted we define \(t_{(u,v)} = \infty\).

Low and High Degree Vertices. Let \(x = 8ck \log(n/\delta)\), for constant \(c\) (where, we assume that \(|S| = O(n^c)|\)). At time \(t\) we say a vertex \(u\) is a \textit{high-degree} vertex if \(d_u > x\); otherwise, if \(d_u \leq x\), we say \(u\) is a \textit{low-degree} vertex.

Data Structures. For every matched vertex \(u\), i.e., \(u \in \mathcal{V}_M\), we maintain an \(x\)-sample recovery sketch \(S_u\) of edges incident on \(u\). We also maintain a dictionary data structure \(T\) of size \(O(k^2)\). We assume the insertion, deletion and query times of \(T\) are all worst-case \(O(\log k)\). At every time \(t\), \(T\) stores edges \((u,v)\) for which vertices \(u\) and \(v\) are matched at time \(t\) (not necessarily to each other); and also edge \((u,v)\) is represented in both sketches \(S_u\) and \(S_v\), i.e. there is a time \(t' \leq t\) at which we invoked \text{UPDATE}(\mathcal{S}_u,(u,v))\), but there is no time in interval \([t',t]\) in which we have invoked \text{UPDATE}(\mathcal{S}_u, - (u,v))\), and symmetrically for \(S_v\).

Sketched Neighbors of a Vertex. Let \(u\) be a matched vertex at some time \(t\), i.e., \(u \in \mathcal{V}_M\). Recall that \(\mathcal{N}_u = \{v \in \mathcal{V} : (u,v) \in E_t\}\) is the full neighborhood of \(u\) at time \(t\). Let \(\mathcal{N}_u' \subseteq \mathcal{N}_u\) be the set of neighbors of \(u\) that up to time \(t\) are inserted to \(S_u\) but not deleted from \(S_u\), that is for every vertex \(v \in \mathcal{N}_u'\) we have invoked \text{UPDATE}(\mathcal{S}_u, (u,v))\) at a time \(t' \leq t\) but have not invoked \text{UPDATE}(\mathcal{S}_u, - (u,v))\) in time interval
We call the vertices in $N'_u$ the sketched neighbors of vertex $u$. Note that we can recover $N'_u$ exactly when $|N'_u| < x$, per Definition 16.

**Invariants.** Recall that at every time $t$ of stream $S$, set $E_t$ is the set of edges which are inserted but not deleted up to time $t$. We develop a dynamic algorithm that at every time $t$ of stream $S$ maintains the following three invariants.

- **Invariant 1:** For every edge $(u,v) \in E_t$ at time $t$ we have at least one of $v \in N'_u$ or $u \in N'_v$.
- Let $(u,v) \in E_t$ be an edge at time $t$ such that $u,v \in V_M$. At time $t$,
  - **Invariant 2:** $u \not\in N'_v$ iff $t_u < t_v$ and $(u,v) \not\in T$.
  - **Invariant 3:** $v \in N'_u$ and $u \in N'_v$ iff $(u,v) \in T$.

Observe that these invariants imply that at any time $|T| < 2k^2$. That is, since $T$ only holds edges such that both ends are matched, and we assume that the matching has at most $2k$ nodes, then the number of edges can be at most $\left(\frac{2k}{2}\right) < 2k^2$.

### 4.3 Adding an Edge to Matching $M$

The first primitive that we develop is Procedure `AddEdgeToMatching((u,v), t)`. This procedure first adds edge $(u,v)$ to matching $M$ and data structure $T$. Then it inserts vertex $u$ to $V_M$, sets timestamp $t_u$ to the current time $t$, and initializes sketch $S_u$ by inserting edge $(u,v)$ to sketch $S_u$. It also repeats these steps for $v$. We invoke this procedure in Procedures Rematch((u,v), t) and Insertion((u,v), t).

**Insertion((u,v), t)**

1. If $u \not\in V_M$ and $v \not\in V_M$, then `AddEdgeToMatching((u,v), t)`.
2. Else `InsertToDS((u,v))`.

**AddEdgeToMatching((u,v), t)**

1. Add edge $(u,v)$ to $M$ and $T$.
2. For $z \in \{u,v\}$
   - a) $V_M \leftarrow V_M \cup \{z\}$
   - b) $t_z \leftarrow t$
   - c) Initialize sketch $S_z$ with `UPDATE(S_z, (u,v))`.

**Lemma 19.** Let $t$ be a time when we invoke Procedure `AddEdgeToMatching((u,v), t)`. Suppose before time $t$, Invariants 1, 2 and 3 hold. Then, Invariants 1, 2 and 3 hold after time $t$.

**Proof.** Recall that $t_u$ is the last time $t' \leq t$ such that $u$ before time $t'$ was unmatched and is matched in the interval $[t', t]$. Similarly, $t_v$ is the last time $t' \leq t$ such that $v$ before time $t'$ was unmatched and is matched in the interval $[t', t]$.

In Procedure `AddEdgeToMatching((u,v), t)` we insert $(u,v)$ to sketches $S_u$ and/or $S_v$ if the edge has not been inserted to these sketches. So, at time $t$, Invariant 1 for edge $(u,v)$ holds. Since $(u,v) \in M$, nothing changes for Invariants 2 and 3. Therefore, if Invariants 2 and 3 hold at time $t - 1$, they also hold at time $t$. □
4.4 Maintenance of Data Structure T

To maintain data structure T at every time t of stream S, we develop two procedures to handle insertions and deletions to the structure. If u and v are matched vertices, Procedure InsertToDS((u, v)) inserts edge (u, v) to sketches Su and Sv as well as to data structure T. If only one of u and v is matched, we insert (u, v) to the sketch of the matched vertex. We invoke this procedure upon insertion of an arbitrary edge (u, v) inside Procedure Insertion((u, v), t).

\[
\text{InsertToDS}((u, v))
\]

1. If \(u \in V_M\) and \(v \in V_M\) then insert edge \((u, v)\) into T.
2. If \(u \in V_M\) then UPDATE(Su, (u, v)).
3. If \(v \in V_M\) then UPDATE(Sv, (u, v)).

Lemma 20. Let \(t\) be a time of stream S when we invoke Procedure InsertToDS((u, v)). Suppose before time \(t\), Invariants 1, 2 and 3 hold. Then, Invariants 1, 2 and 3 hold after time \(t\).

Proof. First assume at time \(t\) when we invoke Procedure InsertToDS((u, v)), vertices u and v are already matched. In Procedure InsertToDS((u, v)) we insert (u, v) to sketches Su and Sv using UPDATE(Su, (u, v)) and UPDATE(Sv, (u, v)). So, \(u \in N'_v\) and \(v \in N'_u\) and Invariant 1 holds. Moreover, we insert \((u, v)\) to T. Therefore, Invariant 3 holds. Invariant 2 also holds as neither condition is true (\(v \notin N'_u\) and \((u, v) \notin T\)).

Next assume only vertex \(u\) is matched. We insert \((u, v)\) to sketch \(S_u\), but not to \(S_v\) and \(T\). Since \(v \in N'_u\), Invariant 1 is correct. Invariant 2 and 3 are correct as \(v\) is not matched at time \(t\). The case when only vertex \(v\) is matched is symmetric.

The second procedure is DeleteFromDS((u, v)) which is invoked in Procedure Deletion((u, v), t) when \((u, v) \notin M\). There are three main cases to consider. If \((u, v) \in T\), we delete \((u, v)\) from sketches \(S_u\) and \(S_v\) as well as data structure \(T\). If not, we know that \((u, v)\) is only in one of \(S_u\) and \(S_v\).

If \(t_u < t_v\) and both \(u\) and \(v\) are matched, we delete the edge from \(S_u\), otherwise, if \(t_v < t_u\) and \(u\) and \(v\) are matched from \(S_v\), we delete the edge from \(S_v\). If none of these cases occur, then only one of \(u\) and \(v\) is matched. If the matched vertex is \(u\), we delete \((u, v)\) from \(S_u\). Otherwise, we delete \((u, v)\) from \(S_v\).

\[
\text{Deletion}((u, v), t)
\]

1. If \((u, v) \in M\) then invoke Rematch((u, v), t)
2. Else invoke DeleteFromDS((u, v)).
3. Invoke AnnounceNeighborhood(u) and AnnounceNeighborhood(v)
DeleteFromDS((u, v))

(1) If (u, v) ∈ T then
   (a) UPDATE(S_u, −(u, v)) and UPDATE(S_v, −(u, v)).
   (b) Remove (u, v) from T.

(2) Else if t_u < t_v and u, v ∈ V_M then UPDATE(S_u, −(u, v)).

(3) Else if t_v < t_u and u, v ∈ V_M then UPDATE(S_v, −(u, v)).

(4) Else if u ∈ V_M and v ∉ V_M then UPDATE(S_u, −(u, v)).

(5) Else if v ∈ V_M and u ∉ V_M then UPDATE(S_v, −(u, v)).

Lemma 21. Assume Invariants 1, 2 and 3 hold at time t when Procedure DeleteFromDS((u, v)) is invoked. Then, Procedure DeleteFromDS((u, v)) chooses the correct case.

Proof. First, we consider the case that both u and v are matched vertices. Since Invariant 3 holds, we know that edge (u, v) at time t is in T if and only if v ∈ N_u' and u ∈ N_v'. Procedure DeleteFromDS((u, v)) searches for (u, v) in T. If this finds (u, v) in T, we then know that v ∈ N_u' and u ∈ N_v'. So, we can safely delete the edge from sketches S_u and S_v and data structure T.

On the other hand, if (u, v) ∉ T, we ensure that the edge is in only one of S_u and S_v. Now, we can use the claim of Invariant 2 which says u ∉ N_v' if and only if t_u < t_v and (u, v) ∉ T. We compare t_u and t_v. If t_u < t_v, then u ∉ N_v'. Recall that since Invariant 1 holds, we know that at least one of v ∈ N_u' and u ∈ N_v' is correct. Because u ∉ N_v', we must have v ∈ N_u'. So deleting edge (u, v) from sketch S_u is the correct operation. On the other hand, if t_v < t_u, then v ∉ N_u' and so edge (u, v) is only in sketch S_v. Thus, deleting edge (u, v) from sketch S_v is the correct operation.

Next, we consider the case that only one of u and v is matched. Let us assume u is the matched vertex. Since Invariant 1 holds, we know that at least one of v ∈ N_u' and u ∈ N_v' is correct. Because u is the matched vertex and we maintain the sketch of matched vertices, (u, v) has been inserted to sketch S_u that is v ∈ N_u'. Therefore, deleting edge (u, v) from sketch S_u is the correct operation. The case when v is the matched vertex is symmetric.

4.5 Announcement and Deletion of Neighborhood of a Vertex

In this section we develop basic primitives for the announcement and deletion of the neighborhood of a vertex. Announcement is performed by Procedure AnnounceNeighborhood(u) which is invoked in Procedure Deletion((u, v), t). Suppose that node u has low degree. For every matched vertex v ∈ N_u', we search for edge (u, v) in T. If (u, v) ∉ T, (u, v) is in both S_u and S_v and no action is needed. But if not, we insert edge (u, v) into tree T as well as sketch S_v.

AnnounceNeighborhood(u)

(1) If u ∈ V_M and d_u ≤ x, then
   (a) For every edge (u, v) in sketch S_u
      i. Add v to set N_u'.
   (b) For every v ∈ N_u' ∩ V_M
      i. If edge (u, v) ∉ T, then insert (u, v) to T; UPDATE(S_v, (u, v)).
We also introduce a deletion primitive in the form of Procedure \textit{DeleteNeighborhood}(u). This is invoked in \textit{Rematch}((u, v), t) when the matched edge (u, v) is removed. The \textit{DeleteNeighborhood}(u) procedure is called on a node u when all the following three conditions hold.

1. The matched edge of matched vertex u is deleted.
2. Vertex u is a low-degree vertex.
3. Vertex u does not have any exposed neighbor.

In this case, we need to delete u from \( V_M \) and delete incident edges on u from data structure \( T \) as Invariant 3 for u is not valid anymore. More precisely, for a low-degree matched vertex whose neighborhood are all matched we do as follows.

We recover all edges from the sketch \( S_u \) (i.e. \( N'_u \)). For every edge \((u, v) \in N'_u \), we check to see if \((u, v) \in T \). If so, we know that \((u, v) \) is represented in both sketches \( S_u \) and \( S_v \). We also delete \((u, v) \) from \( T \) as u is not matched and Invariant 3 does not hold. But if \((u, v) \notin T \), since Invariant 1 holds we know that \((u, v) \) is inserted only in \( S_u \) not in \( S_v \). Observe that since u does not have any exposed neighbor, vertex v must be a matched vertex, and so vertex v has an associated sketch \( S_v \). Therefore, in order to fulfill Invariant 1, we first insert \((u, v) \) to sketch \( S_v \). Finally, we delete the whole sketch \( S_u \), and remove u from \( V_M \).

\begin{algorithm}
\textbf{DeleteNeighborhood}(u)
\begin{enumerate}
  \item For every edge \((u, v) \) in sketch \( S_u \)
    \begin{enumerate}
      \item If edge \((u, v) \in T \) then Remove \((u, v) \) from \( T \).
      \item Else Update\((S_v, (u, v))\).
    \end{enumerate}
  \item Delete sketch \( S_u \) and remove u from \( V_M \).
\end{enumerate}
\end{algorithm}

\textbf{Lemma 22.} Let t be a time when we invoke Procedure \textit{AnnounceNeighborhood}(u). Suppose u is a low-degree matched vertex at time t. Suppose before time t, Invariants 1, 2 and 3 hold. Then after time t, Invariants 1, 2 and 3 hold.

\textbf{Proof.} Let \( N'_u \) be the set of neighbors of u that up to time t are inserted into sketch \( S_u \) but not deleted from \( S_u \). Since u at time t is a low-degree vertex we can use Definition 16 to recover \( N'_u \) in its entirety. We assume Invariants 1, 2 and 3 hold before time t. We prove that all three invariants continue to hold after invocation of \textit{AnnounceNeighborhood}(u).

Fix a matched neighbor \( v \) of u in \( N'_u \) that is \( v \in V_M \cap N'_u \). In Procedure \textit{AnnounceNeighborhood}(u) for \( v \) we do the following. If edge \((u, v) \) has not been already inserted in \( T \), we insert edge \((u, v) \) to \( T \) and \( S_v \). So, now \( v \in N'_u \) and \( u \in N'_u \), and \((u, v) \in T \). Invariants 1, 2 and 3 hold for \((u, v) \), and continue to hold for all other edges. \hfill \Box

After processing this deletion, edge \((u, v) \) is no longer in \( E_t \), and so the invariants trivially hold in regard of this edge. Meanwhile, for any other edge, if the invariants held before, then they continue to hold, since the changes only affected edge \((u, v) \).

\textbf{Lemma 23.} Suppose before time t, Invariants 1, 2 and 3 hold and we invoke \textit{DeleteNeighborhood}(u) at time t. Here we assume u is a matched vertex whose neighbors are all matched, i.e., \( N_u \cap \overline{V}_M = \emptyset \). Then after time t, Invariants 1, 2 and 3 hold.
Proof: Let \((u, v)\) be an edge in sketch \(S_u\). Since we assume Invariant 1 holds before time \(t\), \((u, v)\) must be inserted into at least one of \(S_u\) and \(S_v\). We know edge \((u, v)\) is in \(S_u\). Since Invariants 2 and 3 hold, we have one of the two following cases.

(i) If edge \((u, v)\) is also inserted to \(S_v\), this means this edge must be in \(T\). In \text{DeleteNeighborhood}(u)\) if edge \((u, v)\) is in \(T\), we delete the edge from \(T\) as well as sketch \(S_u\). As \((u, v)\) is still in \(S_v\), Invariant 1 after time \(t\) holds.

(ii) Else, edge \((u, v)\) is not in \(S_v\). Using Invariant 2 this happens if and only if \(t_u < t_v\) and \((u, v) \notin T\). We want to delete all edges which are inserted to \(S_u\) and delete sketch \(S_u\). Observe that since \(u\) does not have any exposed neighbor, vertex \(v\) must be a matched vertex and so has an associated sketch \(S_v\). We insert \((u, v)\) to sketch \(S_v\), and subsequently \(S_u\) is deleted. Therefore, Invariant 1 still holds.

Finally, Invariants 2 and 3 hold after time \(t\) since \(u\) is not a matched vertex anymore. 

\[\Box\]

4.6 Rematching Matched Vertices

In this section we develop the last (and most involved) primitive, Rematch\(((u, v), t)\). We invoke this procedure in Procedure \text{Deletion}((u, v), t)\) when the matched edge \((u, v)\) is deleted. We first delete edge \((u, v)\) from sketches \(S_u\) and \(S_v\) as well as data structure \(T\). We also delete \((u, v)\) from current set \(M\) of matched edges. To see if we can rematch \(u\) and \(v\) to one of their exposed neighbors, we perform the subsequent steps for \(u\) (and then repeat for \(v\)).

If \(u\) is a low degree vertex, by querying \(S_u\) we recover \(N'_u\), i.e., the set of neighbors of \(u\) that up to time \(t\) are inserted into sketch \(S_u\) but not deleted from \(S_u\). We then check whether there is an exposed vertex \(z \in N'_u\). If so, we rematch \(u\) to \(z\).

But if there is no exposed vertex in \(N'_u\), we announce \(u\) as an exposed vertex. We also remove sketch \(S_u\) as \(u\) is not a matched vertex anymore. Moreover, we remove all incident edges on \(u\) from \(T\) as our third invariant does not hold anymore. Lemma 24 shows that in both cases, the matching after invoking Procedure \text{Rematch}((u, v), t)\) is maximal if the matching before this invocation was maximal.

If \(u\) is a high degree vertex, it samples an edge \((u, z)\) from sketch \(S_u\). In Lemma 25 we show that with high probability \(z\) is an exposed vertex, so we rematch \(u\) to \(z\). Therefore, if the matching before the invocation of Procedure \text{Rematch}((u, v), t)\) is maximal, the matching after this invocation would be maximal as well.

\begin{verbatim}
Rematch((u, v), t)
(1) DeleteFromDS((u, v)), remove (u, v) from M, remove u, v from V_M
(2) For w \in {u, v}
    (a) If \(d_w \leq x\) then
        i. For every edge \((w, z)\) in sketch \(S_w\), add \(z\) to set \(N'_w\).
        ii. If there is an exposed \(z \in N'_w\) then invoke AddEdgeToMatching((w, z), t).
        iii. Else invoke DeleteNeighborhood(vertex w).
    (b) If \(d_w > x\) then
        i. Query edges \((w, z_1), \cdots, (w, z_y)\) from sketch \(S_w\) for \(y = 8c \log(n/\delta)\).
        ii. If there is an exposed \(z \in \{z_1, \cdots, z_y\}\) then invoke AddEdgeToMatching((w, z), t).
\end{verbatim}
4.6.1 Analyzing Rematching of a Low-Degree Vertex.

**Lemma 24.** Let \( u \) be a low-degree matched vertex at time \( t \). Assuming the matching \( M \) before time \( t \) is maximal, then, after the invocation of Procedure Rematch((u, v), t), the matching \( M \) is maximal. The running time of Procedure Rematch((u, v), t) when \( u \) is a low-degree vertex is \( O(k \log^4(n/\delta)) \).

**Proof.** Let \( N'_u \) be the set of neighbors of \( u \) up to time \( t \) that are inserted into sketch \( S_u \) but not deleted from \( S_u \). From Definition 16 by querying \( S_u \) and with probability at least \( 1 - \frac{k}{2n^2} \), we can recover \( N'_u \). Observe that assuming Invariants 1, 2 and 3 hold, we must have \( N_u \setminus N'_u \subseteq V_M \), that is, those neighbors of \( u \) that are not in \( N_u' \) at time \( t \) must be matched. Therefore, all exposed neighbors of \( u \) must be in \( N_u' \).

Two cases can occur. The first is if there is an exposed vertex \( z \) in \( N'_u \). Then, Procedure Rematch((u, v), t) will rematch \( u \) using exposed vertex \( z \). The second is when all neighbors of \( u \) are already matched. Since all neighbors of \( u \) are matched, vertex \( u \) cannot be matched to one of its neighbors and so we announce \( u \) as an exposed vertex and release its sketch \( S_u \). Therefore, assuming \( M \) before time \( t \) is maximal, \( M \) after time \( t \) would be maximal as well.

We next discuss the running time of Procedure Rematch((u, v), t) when \( u \) is a low-degree vertex. By properties of the sketch data structures, the time to query \( x \) sampled edges from sketch \( S_u \) and construct set \( N'_u \) is \( O(x \log^2 n \log(n/\delta)) \). If the second case happens, since we assume at every time of stream \( S \), \( |M| \leq k \), we then have \( d_u = |N'_u| \leq 2k \).

Recall that \( T \) is a data structure with at most \( k^2 \) edges whose space is \( O(k^2) \). The insertion, deletion and search times of \( T \) are all worst-case \( O(\log k) \). In the second case, the main cost is to remove incident edges on \( u \) from \( T \). For every neighbor \( z \in N'_u \) we search, in time \( O(\log k) \), if edge \((u, z)\) has been inserted into \( T \); so overall the deletion of incident edges on \( u \) from \( T \) is done in time \( O(k \log k) = O(x \log k) \) as \( |N'_u| \leq 2k \). Overall, the running time of Procedure Rematch((u, v), t) when \( u \) is a low-degree vertex is \( O(x \log^2 n \log(n/\delta)) = O(k \log^4(n/\delta)) \), as we set \( x = O(k \log(n/\delta)) \). \( \square \)

4.6.2 Analyzing Rematching of a High-Degree Vertex.

**Lemma 25.** Let \( x = 8ck \log(n/\delta) \) and \( y = 8c \log(n/\delta) \). Let \( u \) be a high degree vertex, i.e., \( d_u > x \). Suppose we query edges \((u, z_1), \cdots, (u, z_i), \cdots, (u, z_y)\) from sketch \( S_u \). The probability that there exists an exposed vertex \( z \in \{z_1, \cdots, z_y\} \) is at least \( 1 - \delta/n^c \). Further, the running time of Procedure Rematch((u, v), t) when \( u \) is a high-degree vertex is \( O(\log^4(n/\delta)) \).

**Proof.** From Definition 14, a \( \ell_0 \)-sampler returns an element \( i \in [n] \) with probability \( Pr[i] = \frac{|x_i|^0}{\ell_0(k)} \) and returns FAIL with probability at most \( \delta \). Using Lemma 15 there exists a linear sketch-based algorithm for \( \ell_0 \)-sampling using \( O(\log^2 n \log \delta^{-1}) \) bits of space.

Sketch \( S_u \) is a \( y \)-sample recovery sketch which means we can recover min\( \{x, d_u\} \) items (here, edges) that are inserted into sketch \( S_u \). We can think of \( S_u \) as \( x \) instances of a \( \ell_0 \)-sampler. Note that in this way the space to implement \( S_u \) would be \( x \) times the space to implement a \( \ell_0 \)-sampler which is \( O(x \log^2 n \log \delta^{-1}) \) bits of space. Each one of these \( x \) \( \ell_0 \)-samplers returns FAIL with probability at most \( \delta \). Using a union bound the probability that \( S_u \) returns FAIL is \( x \delta \). We rescale the failure probability \( \delta \) to \( \frac{\delta}{2n^c} \) for a constant \( c \). Therefore, the probability that sketch \( S_u \) returns FAIL is \( \frac{\delta}{2n^c} \), and hence the overall space of \( S_u \) is \( O(x \log^2 n \log(xn^c/\delta)) = O(cx \log^2 n \log(n/\delta) + \log \log(n/\delta)) = O(cx \log^2 n \log^2(n/\delta)) \) as \( x = x = 8ck \log(n/\delta) \) and \( k \leq n \).

Let \((u, z_1), \cdots, (u, z_i), \cdots, (u, z_y)\) be the edges queried from sketch \( S_u \) for \( y = 8c \log(n/\delta) \). Note that the time to query \( y \) edges from sketch \( S_u \) is \( O(y \log^2 n \log(n/\delta)) = O(\log^4(n/\delta)) \). Let us define event NoFAIL if \( S_u \) does not return FAIL. Let us condition on event NoFAIL which happens with probability \( \Pr[\text{NoFAIL}] \geq 1 - \frac{\delta}{2n^c} \).
Fix a returned edge \((u, z_i)\). Recall that \(\mathcal{N}_u\) is the neighborhood of \(u\) that is, \(\mathcal{N}_u = \{v \in V : (u, v) \in E_t\}\). The number of matched vertices is at most \(2k\), i.e., \(|V_M| \leq 2k\). Thus, \(|\mathcal{N}_u \cap V_M| \leq 2k\) and \(|\mathcal{N}_u \setminus \mathcal{N}_u'| = |\mathcal{N}_u| - |\mathcal{N}_u'| \leq 2k\). The probability that \((u, z_i)\) is a fixed edge \((u, z)\) is \(\Pr[(u, z_i) = (u, z)] = \Pr[z_i = z] = \frac{1}{|\mathcal{N}_u'| \leq 2k} = \frac{1}{d_u - 2k}\). Using a union bound and since \(d_u > x = 8ck\log(n/\delta)\) we obtain

\[
\Pr[z_i \in V_M] \leq \sum_{y \in \mathcal{N}_u' \cap V_M} \Pr[z_i = y] \leq \sum_{y \in \mathcal{N}_u' \cap V_M} \frac{1}{d_u - 2k} \leq \frac{2k}{d_u - 2k} \leq \frac{1}{2c\log(n/\delta)} \leq \frac{1}{2c}.
\]

Therefore the probability that \(z_i\) is an exposed vertex, i.e., \(z_i \notin V_M\) is \(\Pr[z_i \notin V_M] \geq 1 - \frac{1}{2c}\).

We define an indicator variable \(I_i\) for queried edge \((u, z_i)\) for \(i \in [y]\) which is one if \(z_i \notin V_M\) and zero otherwise. Note that \(\Pr[I_i = 1] \geq 1 - \frac{1}{2c}\). Let \(I = \sum_{i=1}^{y} I_i\). Then, since \(y\) \(\ell_0\)-samplers of \(S_u\) use independent hash functions we obtain

\[
\Pr[I = 0] = \Pr[z_i \in V_M \land \cdots \land z_i \in V_M \land \cdots \land z_i \in V_M] = \prod_{i=1}^{y} \Pr[z_i \in V_M] \leq \left(\frac{1}{2c}\right)^y = \left(\frac{1}{2c}\right)^{8c\log(n/\delta)} \leq \frac{\delta}{2^n}.
\]

Therefore, the probability that there exists an exposed vertex \(z \in \{z_1, \ldots, z_y\}\) is \(1 - \frac{\delta}{2^n}\). Overall, the probability that sketch \(S_u\) does not return FAIL and there exists an exposed vertex \(z \in \{z_1, \ldots, z_y\}\) is

\[
\Pr[\text{NoFAIL} \land \{z_1, \ldots, z_y\} \subseteq V_M] = 1 - \frac{\delta}{2^n}.
\]

\[\Box\]

**Lemma 26.** Suppose that we invoke \(\text{Rematch}((u, v), t)\), and before time \(t\), Invariants 1, 2 and 3 hold, and matching \(M\) is maximal. Then after time \(t\), Invariants 1, 2 and 3 hold and matching \(M\) is maximal. The running time of \(\text{Rematch}((u, v), t)\) is \(O(k\log^4(n/\delta))\).

**Proof.** First of all, we invoke \(\text{AddEdgeToMatching}((u, v), t)\) to add edge \((u, v)\) to matching \(M\). In Procedure \(\text{AddEdgeToMatching}((u, v), t')\), we insert the edge to \(M\) as well as \(T\) for some \(t' \leq t\). We also insert \((u, v)\) to the sketch of whichever vertex \((u\) or \(v)\) was exposed before time \(t'\). So at the end of \(\text{AddEdgeToMatching}((u, v), t')\), \((u, v)\) is in \(S_u, S_v\) and \(T\).

Once we invoke, Procedure \(\text{DeleteFromDS}((u, v))\), it deletes edge \((u, v)\) from \(S_u, S_v\) and \(T\). We also delete the edge from \(M\). So after invocation of \(\text{DeleteFromDS}((u, v))\), Invariants 1, 2 and 3 hold. Let us fix vertex \(u\). The following proof is the same for vertex \(v\). We consider two cases for \(u\).

(i) First, \(u\) is a low-degree vertex, i.e., \(d_u \leq x\) assuming Invariants 1, 2 and 3 hold. Observe that using Lemma 24 after the invocation of Procedure \(\text{Rematch}((u, v), t)\), matching \(M\) is maximal. Moreover, the running time of \(\text{Rematch}((u, v), t)\) when \(u\) is a low-degree vertex is \(O(x\log^2 n \log(n/\delta)) = O(x\log^3(n/\delta))\). Let \(\mathcal{N}_u'\) be the set of neighbors of \(u\) that are inserted into sketch \(S_u\) but not deleted from \(S_u\). By Definition 16 by querying \(S_u\) and with probability at least \(1 - \frac{\delta}{2^n}\), we can recover \(\mathcal{N}_u'\).

Observe that assuming Invariants 1, 2 and 3 hold, we must have \((\mathcal{N}_u \setminus \mathcal{N}_u') \subseteq V_M\). That is, those neighbors of \(u\) that are not in \(\mathcal{N}_u'\) at time \(t\) must be matched. Therefore, all exposed neighbors of \(u\) must be in \(\mathcal{N}_u'\). We have two sub-cases. First, if there is an exposed \(z \in \mathcal{N}_u'\) then we invoke \(\text{AddEdgeToMatching}((w, z), t)\). Lemma 19 shows that Invariants 1, 2 and 3 hold after invocation of \(\text{AddEdgeToMatching}((w, z), t)\). The second sub-case is if there is no exposed node in \(\mathcal{N}_u'\), we then invoke \(\text{DeleteNeighborhood}(\text{vertex } w)\). Lemma 23 shows that Invariants 1, 2 and 3 hold after invocation of \(\text{DeleteNeighborhood}(\text{vertex } w)\).
(ii) Second, \( u \) is a high-degree vertex assuming Invariants 1, 2 and 3 hold. Observe that using Lemma 25 after the invocation of Procedure \text{Rematch}((u, v), t), matching \( M \) with probability at least \( 1 - \delta/n^4 \) is maximal and the running time of Procedure \text{Rematch}((u, v), t) when \( u \) is a high-degree vertex is \( O(\log^4(n/\delta)) \). Since with probability at least \( 1 - \delta/n^4 \) there exists an exposed vertex \( z \in \{z_1, \ldots, z_u\} \), with this probability we invoke \text{AddEdgeToMatching}((w, z), t). Lemma 19 then shows that Invariants 1, 2 and 3 hold after invocation of \text{AddEdgeToMatching}((w, z), t).

\[ \square \]

### 4.7 Completing the Proof of Theorem 10

First we prove the claim for the space complexity of our algorithm. We maintain at most 2\( k \) sketches (for matched vertices), each one is an \( x \)-sample recovery sketch for \( x = 8ck \log(n/\delta) \). From Definition 16 and the proof of Lemma 26, the space to maintain an \( x \)-sample recovery sketch is \( O(k \log^4(n/\delta)) \). So, we need \( O(k^2 \log^4(n/\delta)) \) bits of space to maintain the sketches of matched vertices. The size of data structure \( T \), i.e., the number of edges stored in \( T \) is \( |T| \leq (2k)^2 \). Thus, overall the space complexity of our algorithm is \( O(k^2 \log^4(n/\delta)) \) bits.

Next we prove the update time and query time of our dynamic algorithm for maximal matching is \( O(k) \). In fact, the deletion or the insertion time of an edge \((u, v)\) is dominated by the running time of most expensive procedures which are \text{AnnounceNeighborhood}(u), \text{DeleteNeighborhood}(u), \text{and Rematch}((u, v), t). The running times of these procedures are also dominated by the time to query at most \( x \) edges from sketches \( S_u \) and \( S_v \) plus the time to search for \( x \) edges in data structure \( T \).

The time to query at most \( x \) edges from sketches \( S_u \) and \( S_v \) using Lemma 26 is \( O(k \log^4(n/\delta)) \). The time to search for \( x \) edges in data structure \( T \) is \( O(x \log k) = O(k \log^2(n/\delta)) \) as we assume the insertion, deletion and query times of \( T \) are all worst-case \( O(\log k) \). Therefore, the update time and query time of our dynamic algorithm for maximal matching is \( O(k \log^4(n/\delta)) \).

Finally, we give the correctness proof of Theorem 10. Observe that since after every time \( t \) of stream \( S \), Invariants 1, 2 and 3 hold, and hence the matching \( M \) is maximal. In fact, since Invariant 1 holds, for every edge \((u, v)\) \( \in E_t \) we have at least one of \( v \in N'_u \) or \( u \in N'_v \) which means \( M \) is maximal. Recall that \( V_M \) is the set of vertices of matched edges in \( M \). Note that for every matched vertex \( u \in V_M \), we maintain an \( x \)-sample recovery sketch \( S_u \).

Next, similar to the algorithm of Theorem 6 (Section 3) we construct a graph \((G_M = (V_M, E_M), k)\). For every matched vertex \( v \), we extract up to \( k \) edges incident on \( v \) from sketch \( S_v \) and store them in set \( E_M \). At the end, we run the kernelization algorithm of Section 3.1 on instance \((G_M = (V_M, E_M), k)\). The rest of proof of correctness of Theorem 10 requires showing that maintaining a maximal matching is sufficient to obtain a kernel for vertex cover, which is what was exactly argued in proof of Theorem 6.

### 5 Dynamic Parameterized Streaming Algorithm (DPSA for VC(\( k \))

In this section we prove Theorem 13 which is restated below:

**Theorem 13** Let \( S \) be a dynamic parameterized stream of insertions and deletions of edges of an underlying graph \( G \). There exists a randomized \((nk, nk + 2^{k^2})\)-DPSA for \( VC(k) \) problem.

**Proof.** Let \( S \) be a stream of insertions and deletions of edges to an underlying graph \( G(V, E) \). We maintain a \( kn \)-sample recovery algorithm (Definition 16), which processes all the edges seen in the stream; we also keep a counter to record the degree of the vertex. At the end of the stream \( S \), we recover a graph \( G' \) by extracting the at most \( kn \) edges from the recovery algorithm data structure, or outputting “NO” if there are more than \( kn \) edges currently in the graph. We then run the kernelization algorithm of Section 3.1 on instance \((G', k)\).
Observe that if a graph has a vertex cover of size at most \( k \), then there can be at most \( nk \) edges. Each node in the cover has degree at most \( n \), and every node must either be in the cover, or be adjacent to a node in the cover. Therefore, if the graph has more than \( nk \) edges, it cannot have a vertex cover of size \( k \). We take advantage of this fact to bound the overall cost of the algorithm in the dynamic case. We maintain a structure which allows us to recover at most \( nk \) edges from the input graph, along with a counter for the current number of “live” edges. This can be implemented using a \( k \)-sample recovery algorithm (Definition 16), or indeed by a deterministic algorithm (e.g. Reed-Solomon syndromes).

The algorithm now proceeds follows. To test for a vertex cover of size \( k \), we first test whether the number of edges is above \( nk \): if so, there can be no such cover, and we can immediately reject. Otherwise, we can recover the full graph, and pass the graph to the standard kernelization algorithm (Section 3.1). The total time for this algorithm is then \( O(nk + 2k^2) \), and the space used is that to store the \( k \)-sample recovery algorithm, which is \( \tilde{O}(nk) \).

This assumes that each edge is inserted at most once, i.e. the same edge is not inserted multiple times without intervening deletion. This assumption can be removed, if we replace the edge counter with a data structure which counts the (approximate) number of distinct edges currently in the data structure. This can provide a constant factor approximation with polylogarithmic space. This is sufficient to determine if the number of edges is greater than \( nk \), and if not, to recover the at most (say) \( 1.01nk \) edges in the graph from the data structure storing the edges, and apply the kernelization algorithm of Section 3.1.

6 Concluding Remarks

By combining techniques of kernelization with randomized sketch structures, we have initiated the study of parameterized streaming algorithms. We considered the widely-studied Vertex Cover problem, and obtained results in three models: insertion only stream, dynamic stream and promised dynamic stream. There are several natural directions for further study. We mention some of the below.

**Dynamic Algorithms.** Recent work has uncovered connections between streaming algorithms and dynamic algorithms [22]. It is natural to ask whether we can make the algorithms provided dynamic: that is, ensure that after each step they provide (implicitly or explicitly) a current answer to the desired problem. The current algorithm for maximal matching sometimes takes time polynomial in \( k \) to process an update: can this be made sublinear in \( k \)?

Our main algorithm in Section 4 applies in the case where there is a promise on the size of the maximal matching. Can this requirement be relaxed? That is, is there a dynamic algorithm that will succeed in finding a maximal matching of size \( k \) at time \( t \), even if some intermediate maximal matching has exceeded this bound? Or can the cost be made proportional to the largest maximal matching encountered, i.e. remove the requirement for \( k \) to be specified at the time, and allow the algorithm to adapt to the input instance.

**Other Problems.** In this paper, we only considered the Vertex Cover problem. We think it is interesting to consider other NP-hard problems in the framework of parameterized streaming, and that kernelization algorithms can be helpful in this endeavour. In some cases, one might be able to obtain parameterized streaming algorithms with simple observations. For example, in the Feedback Vertex Set (FVS(\( k \))) problem, we are given a graph \( G = (V, E) \) and an integer \( k \). The question is whether there exists a set \( V' \subseteq V \) such that \( G \setminus V' \) has no cycles. We can show the following results (proved in the appendix) for FVS(\( k \)):

**Theorem 27.** There is a deterministic PSA for FVS(\( k \)) which uses \( O(nk) \) space.

**Theorem 28.** Any (randomized) PSA for FVS(\( k \)) requires \( \Omega(n) \) space.

**Acknowledgments.** The third author would like to thank Marek Cygan for fruitful discussion on early stages
of this project in a Dagstuhl workshop. We thank Catalin Tiseanu for some useful discussions regarding the Feedback Vertex Set problem.

A Feedback Vertex Set

In this section, we prove Theorem 27 and Theorem 28.
A.1 Parameterized Streaming Algorithm (PSA) for FVS(k)

We restate and prove Theorem 27 below:

**Theorem 27.** There is a deterministic PSA for FVS(k) which uses $O(nk)$ space.

**Proof.** To prove Theorem 27 we use the following lemma bounds the number of edges of a graph with small feedback vertex set.

**Lemma 29.** Any graph with a feedback vertex set of size at most $k$ can have at most $n(k + 1)$ edges, where $n$ is the number of vertices of the graph.

**Proof.** Let the graph be $V = (G, E)$ and $S \subseteq V$ be the feedback vertex set of size at most $k$. Then the graph $G \setminus S$ is a forest, and hence has at most $n - |S| - 1$ edges. Now each of the vertices in $S$ is adjacent to at most $n - 1$ vertices in $G$. Hence the total number of edges of $G$ is at most $(n - |S| - 1) + (n - 1)|S| = n + (n - 2)|S| - 1 \leq n + nk$ since $|S| \leq k$.

The PSA algorithm for FVS(k) runs as follows:

- Store all the edges that appear in the stream.
- If the number of edges exceeds $n(k + 1)$, output NO.
- Otherwise the total number of edges (and hence the space complexity) is $n + nk$. Now that we have stored the entire graph, use any one of the various known FPT algorithms [7, 23] to solve the FVS(k) problem.

This concludes the proof of Theorem 27.

A.2 $\Omega(n)$ Lower Bound for FVS(k)

We restate and prove Theorem 28 below:

**Theorem 28.** Any (randomized) PSA for FVS(k) requires $\Omega(n)$ space.

**Proof.** We show the proof by reduction to the Disjointness problem in communication complexity.

**DISJOINTNESS**

*Input:* Alice has a string $x \in \{0, 1\}^n$ given by $x_1x_2 \ldots x_n$.
Bob has a string $y \in \{0, 1\}^n$.

*Question:* Bob wants to check if $\exists i : x_i = y_i = 1$. 

24
There is a lower bound of \( \Omega(n) \) bits of communication between Alice and Bob, even allowing randomization [24].

Given an instance of Disjointness, we create a graph on \( 8n \) nodes as follows. We create nodes \( \alpha_i, \beta_i, \ldots, \eta_i \), and insert edges \( (b_i, g_i), (c_i, e_i), (d_i, f_i) \) for all \( i \). We also create edges \( (h_i, \alpha_{i+1}) \) for \( 1 \leq i < n \). This is illustrated in the first graph in Figure 1.

For each \( i \), we add 2 edges corresponding to \( x_i \), and two according to \( y_i \). If \( x_i = 0 \), we add \( (a_i, c_i) \) and \( (b_i, d_i) \); else we add \( (a_i, b_i) \) and \( (c_i, d_i) \). If \( y_i = 0 \), we add \( (f_i, h_i) \) and \( (e_i, g_i) \); else we add \( (f_i, e_i) \) and \( (g_i, h_i) \).

We now observe that the resulting graph is a tree (in fact it is a path) if the two strings are disjoint, but it has at least one cycle if there is any \( i \) such that \( x_i = y_i = 1 \). This can be seen by inspecting Figure 1 which shows the configuration for each possibility for \( x_i \) and \( y_i \). Thus, any streaming algorithm that can determine whether a graph stream is cycle-free or has one (or more) cycles implies a communication protocol for Disjointness, and hence requires \( \Omega(n) \) space.

Since FVS(k) must, in the extreme case \( k = 0 \), determine whether \( G \) is acyclic, then \( \Omega(n) \) space is required for this problem also. This generalizes to any constant \( k \) by simply adding \( k \) triangles on \( 3k \) new nodes to the graph: one node from each must be removed, leaving the question whether the original graph is acyclic.
