ABSTRACT

We report the discovery of large amounts of cold ($T \sim 10^4$ K), chemically young gas in an overdensity of galaxies at redshift $z \sim 1.6$ located in the Great Observatories Origins Deep Survey southern field. The gas is identified thanks to the ultra-strong Mg II $\lambda 2800$ absorption features it imprints onto the rest-frame UV spectra of galaxies in the background of the overdensity. There is no evidence that the optically thick gas is part of any massive galaxy (i.e., $M_{\text{vir}} > 4 \times 10^9 M_\odot$), but rather is associated with the overdensity; less massive and fainter galaxies $(25.5 \text{ mag} < z < 27.5 \text{ mag})$ have too large an impact parameter to be causing ultra-strong absorption systems, based on our knowledge of such systems. The lack of corresponding Fe II absorption features, not detected even in co-added spectra, suggests that the gas is chemically more pristine than the interstellar medium and outflows of star-forming galaxies at redshift similar to, including the galaxies of the overdensity itself, and comparable to the most metal-poor stars in the Milky Way halo. A crude estimate of the projected covering factor of the high-column-density gas ($N_H \gtrsim 10^{20} \text{ cm}^{-2}$) based on the observed fraction of galaxies with ultra-strong absorbers is $C_F \approx 0.04$. A broad, continuum absorption profile extending to the red of the interstellar Mg II absorption line by $\lesssim 2000 \text{ km} \text{ s}^{-1}$ is possibly detected in two independent co-added spectra of galaxies belonging to the overdensity, consistent with a large-scale infall motion of the gas onto the overdensity and its galaxies. Overall, these findings provide the first tentative evidence of accretion of cold, chemically young gas onto galaxies at high redshift, possibly feeding their star formation activity. We suggest the fact that the galaxies are members of a large structure, as opposed to field galaxies, might play a significant role in our ability to detect the accreting gas.

1. INTRODUCTION

The history of gas accretion in galaxies is a major outstanding question that is essentially unconstrained by the empirical investigation. Do galaxies evolve by transforming into stars the mass of gas present in their hosting halo at the time of its formation? Or do they continue accreting substantial amounts of gas from the environment to feed star formation?

Theoretically, an interesting recent development is the realization that most of the baryonic mass in galaxies of all masses is supposed to accrete as relatively cold gas, namely, gas that was never shock heated to the halo virial temperature (e.g., Birnboim & Dekel 2003; Keres et al. 2005, 2009; Dekel & Birnboim 2006; Dekel et al. 2009a, and references therein). Current hydrodynamical simulations show that halos with mass below the threshold value $M_{\text{thr}} \sim (2-3) \times 10^{11} M_\odot$ acquire their gas primarily by cold accretion, with hot accretion remaining relatively unimportant in providing gas for star formation. More massive halos do acquire an atmosphere of hot coronal gas in the simulations which subsequently cools and contributes to star formation, but cold accretion remains nonetheless the dominant mode of gas acquisition, even in this case, at high redshift (e.g., $z \gtrsim 2$), while hot accretion starts to compete only at $z < 1$.

Observationally, there has been scant evidence for galactic-scale accretion so far, cold or otherwise, with powerful and ubiquitous outflows powered by star formation being the only bulk motions of gas in the proximity of galaxies that have been unambiguously detected at low and high redshifts (e.g., Steidel et al. 1996; Pettini et al. 2001; Shapley et al. 2003; Tremonti et al. 2007; Weiner et al. 2009; Nestor et al. 2011). Rauch et al. (2008) reported detection of Ly$\alpha$ emission around galaxies at $z \sim 3$ which they interpret as possible evidence of accreting H I gas onto these systems. Steidel et al. (2010) find evidence of possible gas inflows around relatively massive galaxies at $z \sim 2$ but conclude that this is not necessarily evidence of cold accretion and other explanations are possible, and, in fact, more likely. Indirect evidence of accretion of chemically pristine gas is reported by Cresci et al. (2010), who interpret the inverse gradient of the metallicity of the nebular gas in star-forming galaxies at $z \sim 3$ as evidence that the metallicity of the central regions is being diluted by accreting cold flows.
It is not straightforward, however, to interpret the absence of evidence of accretion as evidence of the absence of accretion. On the one hand, we do not have much insight into the relative covering factor of high-column-density inflowing gas, i.e., observable in relatively low signal-to-noise ratio (S/N) absorption systems, versus the outflowing one. For example, the simulations predict the geometry of the cold gas to be largely filamentary over scales ranging from $10^2$ kpc to $\sim$1 Mpc (Dekel et al. 2009a), in particular before they enter the "sphere of influence" of the accreting galaxy (the circumgalactic medium, or CGM, in recent parlance). At closer galactocentric distance, which is where current observations are probing the interstellar medium (ISM), the smooth accreting flow is expected to break into a lumpier distribution of cold gas, especially around more massive halos (Keres & Hernquist 2009; Dekel et al. 2009b), which in turn feeds clumpy, unstable disks. If this is a fair description of reality, then the total cross section of high-column-density accreting gas, especially in the proximity of the star-forming regions, should be relatively small, as suggested in recent works (Fumagalli et al. 2011; Ceverino et al. 2010; Kimm et al. 2010; A. Dekel 2010, private communication) which calculate that the covering factor of gas with $N_H < 10^{20}$ cm$^{-2}$ around $M \sim 10^{12}$ $M_\odot$ halos is $C_F \lesssim 3\%$, and that of gas with $10^{20}$ cm$^{-2} < N_H < 10^{21}$ cm$^{-2}$ is $C_F \lesssim 1\%$.

On the other hand, there is the distinct possibility that we do not fully understand the inherent bias and limitations of the current observations of the CGM of distant galaxies, as far as the detection of gas accretion is concerned. For example, the observations by Steidel et al. (2010) probe the gas along sight lines toward, and in some cases in the proximity ($\lesssim 150$ kpc) of, regions of powerful star formation, with the UV-bright regions of the galaxies providing the back-illumination to study the gas in absorption. The galaxies are selected to be star-forming ones with moderate or no dust obscuration. These selection criteria might preferentially yield samples of galaxies oriented along the least obscured line of sight from the observer toward their center, thus biasing their studies to finding strong signature of outflows with high covering factor.

In general, outflows from star-forming galaxies cover large solid angles (Tremonti et al. 2007; Martin 2006), and it is possible that their interactions with the inflowing gas, as well as the sensitivity of the observations, conspire against the detectability of inflows, because the strength of the interstellar absorption is generally very strong and broad in velocity space, and can completely dilute and hide the signal of the inflow (Kimm et al. 2010). Unfortunately, the simulations do not yet provide firm predictions on the observability (with current technology) of the inflowing of gas and how this interacts with the outflowing one, especially in the volumes at small impact parameters from the galaxies’ centers that have been targeted by the observations so far.

Until we gain firmer theoretical guidance on the effective cross section of the accreting gas and its observability in the proximity of galaxies, an important first step would be to constrain the abundance of gas at large galactocentric distance that can plausibly feed accretion. Indeed, staying well clear of the regions directly affected by the outflows seems a promising strategy, since the gas must reach the accreting galaxies from large distances, and in this way one would eliminate the inherent complications of having to disentangle and interpret the kinematics of gas that participates in inflows as well as outflows. The challenge of such a strategy is to overcome the small cross section of high-column-density gas, if this is to be detected by means of absorption spectroscopy. This might appear to be a daunting task, especially if the theory is right that, at large separations from galaxies, the accreting flows exhibit filamentary geometry. Cosmological simulations, however, suggest, at least qualitatively, that the projected cross section of gas accreting onto large cosmic structures is proportionally larger than in the case of isolated galaxies. The simulations also show that the covering fraction of the gas increases with the halo mass. Thus, targeting the relatively common “overdensities” of galaxies, nearly ubiquitous in any redshift survey as “spikes” in the galaxies’ redshift distribution, might currently be our best hope to gain some insight into the issue of “cold accretion” since they might provide sufficient cross section of high-column-density gas. The most massive among these overdensities typically extend over wide regions of space, with linear size of a few tens Mpc, which means that a relatively large number of bright background galaxies are generally available to back-illuminate the gas and make it visible by means of spectroscopy of the intervening absorption systems.

In this paper we report the discovery of large amounts of cold gas, i.e., $T \sim 10^4$ K, not directly associated with any galaxies, in a large overdensity of galaxies at $z \approx 1.6$ located in the Great Observatories Origins Deep Survey southern (GOODS-S) field (see Kurk et al. 2009). The gas is detected thanks to the Mg II $\lambda\lambda 2797, 2803$ absorption features it imprints onto the individual spectra of background Lyman break galaxies (LBGs) at $z \sim 3$, as well in the stacked spectra of other background galaxies. It appears to be chemically more pristine than that observed in the outflows of star-forming galaxies at the same redshift, including those within the same overdensity. We discuss the observed and inferred properties of the gas and the tentative evidence that it accretes onto at least some of the overdensity galaxies. Throughout this paper, when needed, we use a cold dark matter world model with Hubble constant $H_0 = 70$ km s$^{-1}$ Mpc$^{-1}$, $\Omega_m = 0.3$, and $\Omega_\Lambda = 0.7$. Magnitudes are in the AB scale of Oke & Gunn (1983).

2. OBSERVATIONS AND DATA SET

The data presented in this paper include spectra of star-forming galaxies in the GOODS-S field, selected from the GOODS Hubble Space Telescope (HST)/Advanced Camera for Surveys (ACS) imaging survey (Giavalisco et al. 2004b) using a number of criteria based on rest-frame UV colors aimed at selecting star-forming galaxies at $z > 1.5$ (see Giavalisco et al. 2004a; Vanzella et al. 2005, 2006, 2008). The ACS mosaic in the GOODS-S field covers an area of roughly $10' \times 16'$, or about $5 \times 8$ Mpc (proper) at $z \approx 1.6$, and has been the target of a number of programs of follow-up spectroscopic observations of HST-selected galaxies using a number of telescope and spectrometer combinations, including the Very Large Telescope (VLT) with VIMOS and FORS2 (Vanzella et al. 2005, 2006, 2008; Popesso et al. 2009; Balestra et al. 2010) and Keck with DEIMOS and LRIS (D. Stern et al. 2011, in preparation); in this work we focus on the spectra obtained with FORS2, which we will refer to as the “GOODS survey.” These include three LBGs at $z \gtrsim 3$ where we have discovered absorption features, the subject of our discussion here, that we identify as due to Mg II at $z \approx 1.6$. These spectra were obtained as part of our program of spectroscopic identifications of LBG candidates selected from the ACS $B_{135} V_{606} I_{775} Z_{580}$ images (Giavalisco et al. 2004a; Vanzella et al. 2009). Acquisition, reduction, and analysis of the spectra have already been presented in the papers above, and we will not discuss them further here.
Figure 1. Observed spectra of the three LBGs at \( z > 3 \) with intervening absorption system at \( z \approx 1.6 \), which we identify as due to Mg\( \text{II} \) (highlighted). The two-dimensional dispersed images have been sky subtracted and wavelength calibrated (in the observed frame). A boxcar-smoothed, optimally extracted spectrum is also shown on top of the two-dimensional spectrum together with the adjacent spectrum of the night sky included in the same slitlet. A spectrum of the night sky is shown at the top of the figure, and major night-sky emission lines are marked as shaded vertical bands.

(A color version of this figure is available in the online journal.)

Other spectroscopic data include the spectra of star-forming galaxies at \( 1.5 < z < 2.5 \) obtained during the “Galaxy Mass Assembly ultra-deep Spectroscopic Survey” (GMASS) survey (Cimatti et al. 2008; Kurk et al. 2009), which have been selected from the GOODS Spitzer/IRAC 4.5 \( \mu \text{m} \) images to satisfy the flux limit \( m_{4.5} \mu \leq 23 \), essentially a mass-limit selection criterion approximately corresponding to \( m_{\text{star}} \geq 2 \times 10^9 \, M_{\odot} \), with a small dependence on the spectral type. The redshift of these galaxies extends up to \( z < 5.5 \) with \( \sim 90\% \) of them having \( z < 2.5 \), and include the redshifts of galaxies that belong to a large overdensity at \( z \approx 1.61 \), which are distributed over a substantial portion of the ACS mosaic, as we will discuss later (Vanzella et al. 2008; Kurk et al. 2009). In the following, we will refer to these redshifts as “the GMASS survey.” Including GMASS and GOODS, there are 97 spectroscopic redshifts and 194 photometric redshifts (Dahlen et al. 2010) in the range \( 1.56 \leq z \leq 1.64 \), which roughly defines the overdensity, satisfying the above mid-IR flux limit criterion, crudely \( \sim 50\% \) spectroscopic completeness in that redshift interval.

Figure 1 shows the observed two-dimensional GOODS spectra of 3 LBGs, out of a total of 21 with \( z_{850} < 24.6 \) that we have analyzed, in which we have detected the presence of absorption features, all of them around \( \lambda \sim 7300 \, \text{Å} \), that do not match any known strong feature at their redshift. These LBGs have originally been selected as “\( B \)-band” dropouts from the GOODS \( HST/ACS \) \( B_{435}V_{606}i_{775}z_{850} \) photometry (Giavalisco et al. 2004a) and marked for follow-up spectroscopy as part of our investigation of galaxies at very high redshift (see Vanzella et al. 2008, 2009 for a discussion of the data reduction and analysis). Figure 2 shows the optimally extracted spectra of the three LBGs with the intervening absorption features marked in red and labeled with the redshift of the trough, if identified as Mg\( \text{II} \). The \( z_{850} \) magnitude and redshift of the LBG are also shown, as well as some of their spectroscopic features.
The dispersion of these spectra is $R \approx 660$, corresponding to a resolution of $\approx 11$ Å, or about 454 km s$^{-1}$ in the observed frame, at the wavelength of the features. The pixel scale along the dispersion direction is $\Delta \lambda = 3.2$ Å.

While all four absorption features have wavelengths within the range of the band of weak night-sky lines located at $7200 \lesssim \lambda \lesssim 7400$ Å, there is no evidence that the features themselves might be due to noisy sky removal. Both the two-dimensional and extracted spectra show that no similar features are observed in spectral regions affected by much stronger night-sky lines, where the continuum of the three LBGs is observed without spurious “absorption lines.” In general, the four LBG absorption features have FWHM consistent with kinematic broadening being comparable to the spectral resolution, except the absorption feature in the spectrum of G3 (see below), which is considerably broader.

Galaxy J033220.85$-$275038.9 (G1 from now on) has apparent magnitude $z_{850} = 24.56$ mag and redshift $z \approx 3.450$, measured from a spectrum with quality flag QF $= B$ in the quality classification system by Vanzella et al. (2009). The quality flag values A, B, and C correspond to redshift identifications that are “unambiguous,” “likely,” e.g., when based on one line only or on a spectral break, and “uncertain,” respectively. As discussed in Vanzella et al. (2008, 2009), we assigned QF $= B$ to G1 because only one strong emission line, interpreted as Ly$\alpha$, is observed in its spectrum; the asymmetric profile of the line, the dimming of the continuum in correspondence of the Ly$\alpha$ forest and the presence of a strong spectral break in an otherwise blue continuum, as shown by its ACS broadband colors, make the redshift identification of this galaxy secure. An absorption line is detected with the central wavelength located at $\lambda = 7246.5 \pm 0.5$ Å, observed equivalent width $W_0 = 20 \pm 4$ Å, and FWHM $= 12 \pm 2$ Å (from a fit to a single-Gaussian line profile). Although the spectrum has relatively low S/N, the two-dimensional spectrum shows that the absorption feature is broader than the night-sky line adjacent to it. The extracted spectrum suggests that the line possibly has an asymmetric profile, with the blue wing broader than the red one.

Galaxy J033226.18$-$275211.3 (or G2) has magnitude $z_{850} = 24.37$ mag, and in Vanzella et al. (2009), we reported its redshift measure as having QF $= C$ and listed the tentative value $z = 3.097$. Since this source shows two absorption systems at around $\lambda \approx 7280$, we have re-analyzed both our FORS2 spectrum and the VIMOS spectrum of this galaxy acquired by Popesso et al. (2009) in an attempt to make a better measure of its redshift. Using the spectrum of cB58, a lensed LBG whose apparent magnitude is unusually bright (Pettini et al. 2002), as a template, a cross-correlation analysis yields $z_F = 3.0950$ from the FORS2 spectrum and $z_V = 3.0954$ from the VIMOS one. In the former case, the redshift is mostly determined by C$\IV$, Fe$\II$, and Al$\II$ absorption lines (these two visible in the portion of the spectrum plotted in Figure 2), while in the latter by Ly$\alpha$, C$\II$, and C$\IV$ features. Two absorption lines inconsistent with known strong features at $z \approx 3$ are observed with central wavelength at
of a barely resolved doublet. The two-dimensional spectrum shows that in both cases the absorption feature is broader than adjacent night-sky lines. The observed equivalent width of the features is \( W_\lambda = 23 \pm 5 \) and \( W_\lambda = 14 \pm 5 \) \( \text{Å} \), respectively, while the width from best fits to single-Gaussian line profiles are \( \text{FWHM} = 21 \pm 2 \) \( \text{Å} \) and \( 24 \pm 2 \) \( \text{Å} \), respectively. The velocity difference between the two absorption lines is \( \approx 3500 \text{ km s}^{-1} \), too large to make us believe that one intervening galactic system (a galaxy and its CGM) might be responsible for producing both of them.

Galaxy J033226.76−275225.9 (G3), with \( z_{580} = 24.10 \) mag and redshift \( z = 3.562 \), has quality flag \( \text{QF} = \text{A} \). Some of the low-ionization metal absorption lines used to determine its redshift are visible in the figure. An absorption line is observed with central wavelength located at \( \lambda = 7331.6 \) \( \text{Å} \) and with equivalent width and line width \( W_\lambda = 26 \pm 7 \) and \( \text{FWHM} = 45 \pm 10 \) \( \text{Å} \), respectively (again, the width comes from a best fit to a single-Gaussian line profile). As in the case of G1, it is possible that the profile of this line is asymmetric, with the bluer part broader than the red one. Finally, also in this case the two-dimensional spectrum does not show any evidence of an anomalous subtraction of the sky emission, and the feature appears to be significantly broader than the night-sky emission lines close to it.

The three LBGs are fairly typical in their variety of spectral properties. Galaxy G1 has strong Lyα in emission and weak interstellar absorption lines, while G2 and G3 have stronger interstellar absorption features and weak or absent Lyα, as very frequently observed in what are termed “emitter” and “absorber” LBGs (see Steidel et al. 1996; Shapley et al. 2003; Vanzella et al. 2009, and discussion therein). On the plane of the sky the three LBGs are roughly aligned along a straight line, oriented approximately at P.A. = −45°; the angular separations between the centroids of the \( z_{580} \)-band images of G1 and G2, G1 and G3, and G2 and G3 are 116.3, 132.6, and 16.5 arcsec, respectively (see Figures 7 and 8). At redshift \( z = 1.61 \) the corresponding projected distances between the line of sight (LOS) to G1 and G2, G1 and G3, and G2 and G3 are \( d_{12} = 986 \), \( d_{13} = 1124 \), and \( d_{23} = 140 \) kpc (physical), respectively. In velocity space, the absorption feature of G1 and the blue of the two features of G2 are separated by \( \Delta V = 580 \) km s\(^{-1} \), while the redder one and the feature of G3 have \( \Delta V = 800 \) km s\(^{-1} \). The separation between the absorption lines of G1 and G3 is \( 3520 \) km s\(^{-1} \), the same as the velocity difference between the two features observed in the spectrum of G2.

3. LARGE AMOUNTS OF \( T \sim 10^4 \) K GAS IN THE OVERTENZY AT \( z \approx 1.61 \)

The three LBGs discussed above share the common property of having absorption features, all located approximately at the same wavelength, \( \lambda \sim 7300 \text{ Å} \), that do not match any known strong spectral feature at their redshifts. These “spurious” lines all match, however, the rest-frame wavelength of Mg ii \( \lambda 2800 \) absorption at the redshift of the intervening galaxy overdensity at \( z \approx 1.61 \). Since no other feature is observed in the spectrum of any of the galaxies that would confirm this interpretation, we have obtained a stacked spectrum by averaging each candidate Mg ii absorption line after shifting its central wavelength to the common rest-frame wavelength \( \lambda = 2800 \) Å. We found that it makes no difference in the result if the spectra are scaled or not before the average is computed, which is reasonable since the galaxies have similar continuum intensities. Thus, the spectrum of galaxy G2 enters twice in the stack, albeit each time with a different wavelength shift, since there are two candidate Mg ii absorption lines in it. Such stacked spectrum is shown in Figure 3 (top spectrum).

The stacked absorption feature has rest-frame equivalent width \( W_\lambda = 6.2 \pm 1.5 \) Å and appears barely resolved into a doublet. We have fit the feature to a two-component Gaussian line profile using a chi-square procedure to measure the central wavelength of each component, finding best-fit values \( \lambda_{G1} = 2796.5 \pm 0.7 \) Å for the blue one and \( \lambda_{G2} = 2803.0 \pm 1 \) Å for the red (we left the central wavelength and line width of both components as free parameters finding the reduced chi-square of the best fit to be \( \chi^2 \approx 1.0 \)). Each component has rest equivalent width \( \sim 3 \) Å, and their, \( \text{FWHM} \approx 4 \) Å, is consistent with kinematic broadening comparable to the spectral resolution, i.e., 200 km s\(^{-1} \) in the rest frame. No Mg ii absorption line is observed in the stacked spectrum, although none is to be expected given the S/N if the ratio of the equivalent width of this line to that of Mg ii is similar to that observed in the galaxy spectra discussed below, i.e., \( \approx 1/6 \).

Since the individual intervening absorption lines in the LBG spectra are detected at a relatively low significance level, in the range \( 3 < \sigma < 5 \), we have further investigated their significance using Monte Carlo simulations. Specifically, we have created a large number of random realizations (5000) of the three LBG spectra by altering each spectrum, pixel by pixel, with a Gaussian variate with zero mean and variance from that spectrum’s error array. To include the uncertainty of the estimate of the value of the continuum in the simulations we have used all pixels in the spectral range 2075 Å \( \leq \lambda \leq 2895 \) Å, which is where the continuum is measured with a linear fit (excluding the absorption line). We have then fitted a Gaussian profile to each intervening absorption feature, leaving the centroid as a free parameter. For each random realization of the three spectra we have also obtained the stack of the four absorption features, following the same procedure adopted for the original spectra. The distributions of the wavelength of the centroid and of the equivalent width of each absorption line in the 5000 realizations of the three LBG spectra are plotted in Figure 4, which shows that in essentially all cases the lines are reproduced with the same centroid wavelength and equivalent width as those measured in the real spectra, within the 1σ scatter. In the case of the absorption line in G1’s spectrum, the centroid of a fraction of the realizations is found at significantly lower wavelength than that of the majority of the realizations, at \( \approx 7235 \) Å, consistent with the lower S/N ratio of this feature compared to the other three. In all the other cases the distributions of the centroid wavelength are well-defined bell-shaped curves. The distributions of the equivalent width of each of the four absorption lines from the simulations, as well as that of their stack, the latter reproduced in Figure 5, are also well-defined bell-shaped curves with width and peak value consistent with the observations.

Finally, we also used simulations to assess the robustness of the detection of a doublet in the stack of the four absorption lines. In general, a two-component Gaussian line profile provides a similarly good or better fit to the simulated data than the single-Gaussian one, but this is to be expected given the low S/N of the spectra and the larger number of free parameters of the two-component Gaussian profile relative to the single one. If we count how often the double-Gaussian model is consistent with the Mg ii doublet, however, we find that only 562 of the 5000 (≈11%) realizations have flux and width ratio of the two components within 50% from each other and with centroid

\[ \lambda_c = 7266.2 \text{ and } 7352.1 \text{ Å} \]
galaxies affected by telluric absorption. The profile of the Mg\textsc{ii}\(\lambda 2796\) components located at a wavelength of each line to the common rest-frame wavelength \(\lambda = 2800\) Å. A partially resolved doublet is clearly observed, with the centers of the blue and red components located at \(\lambda = 2796.7\) Å and \(\lambda = 2801.5\) Å, respectively, and total rest equivalent width \(W_r = 6.3 \pm 1.5\) Å. No other absorption feature is observed in the stacked spectrum down to a 1σ equivalent width limit of 1.5 Å. No other absorption feature is observed in the stacked spectrum down to a 1σ equivalent width limit of 1.5 Å.

The blueshifting signature of the outflows is not observed in the 16 GOODS overdensity galaxies (spectrum (c) in Figure 3), which is also marginally resolved.9 The two co-added spectra have comparable S/N characteristics, S/N ≈ 8 and \(\approx 12\) per resolution element, respectively, thus suggesting that the doublet profile of the stack of the four LBG absorption lines is real. Clearly, spectra with higher S/N are necessary to solve this issue.

Figure 3 also compares the co-added spectrum of the four Mg\textsc{ii} absorbers to those of star-forming galaxies in the\(z\approx 1.61\) overdensity as well as at \(z \sim 0\), where Mg\textsc{ii} and other absorption features, such as Fe\textsc{ii}, are produced in the galaxies’ ISM, including outflows, and the gas is illuminated by the UV light from massive stars located in the galaxies themselves. As in the case of the LBG, we have found that the stacked spectra are insensitive to scaling the continuum of the individual spectra prior to calculating their average. The most striking difference between the stacked spectrum of the LBG and those of the galaxies is the systematic absence of Fe\textsc{ii} absorption in the latter, while none is detected in the former. Finally, we point out that the Mg\textsc{ii} and Fe\textsc{ii} absorption lines in the stacked spectrum of the 16 GOODS overdensity galaxies (spectrum (c) in Figure 3) are clearly systematically blueshifted by \(\approx 250\) km s\(^{-1}\) relative to the systemic redshift, which is traced by the nebular emission lines (in all cases the individual galaxy spectra are placed in the rest frame using the redshift of the [O\textsc{iii}] \(\lambda 3727\) emission line). This is evidence that the gas participates in outflows, very likely powered by the activity of star formation. The blueshifting signature of the outflows is not observed in the\(z \sim 1.9\) and \(z \sim 0\) co-added spectra, because in this case the redshift of the individual galaxies is measured from the Mg\textsc{ii} and Fe\textsc{ii} absorption features themselves, since the [O\textsc{iii}] line is outside of the available spectral range.

There is a hint that the Mg\textsc{ii} absorption in the stacked spectrum of \(z \approx 1.61\) overdensity galaxies also includes a broader, asymmetric component that extends to the red of the doublet, with may be even additional narrow discrete components (marked by short vertical segments) overimposed outside of the available spectral range.

---

9 The identification of this feature as the Mg\textsc{ii} doublet seems beyond question. The Fe\textsc{ii} \(\lambda 2344, \lambda 2382\) absorption lines and the Fe\textsc{ii} \(\lambda 2396\) emission line are clearly detected in the stacked spectrum. The Fe\textsc{ii} \(\lambda 2587, \lambda 2600\) and Mg\textsc{i} \(\lambda 2852\) absorption lines are marginally detected if considered individually, but the fact that all these features are simultaneously observed as absorption features at the correct wavelength provides further evidence that the identification of the spectral features is correct.
onto it. If real, this would be the signature of gas located in front of the galaxies and moving toward them, since the putative absorbing gas cloud is back-illuminated by the galaxies' starlight and its absorption feature is redshifted relative to the primary one. A similar kinematical structure is observed in neither of the two Fe absorption features, which are both detected with relatively higher S/N and whose wavelength is located in a spectral region where the night-sky emission is significantly fainter. It is not observed in the stacked spectrum of the four LBG absorption systems, whose S/N is lower and which are observed in the same spectral region as that of the \( z \approx 1.61 \) galaxies, thus subject to the same night-sky emission. In view of the implications that such evidence, if confirmed, would have, we will discuss it in more detail in the next section.

We have further investigated the presence of “intra-overdensity” gas using the deeper GMASS spectra. Specifically, we have co-added together the spectra of galaxies with redshift \( z > 1.65 \), namely, in the background of the \( z \approx 1.61 \) overdensity but distributed along the same LOS. We have selected a total of 92 “background” galaxies from the GMASS survey, which have apparent magnitude \( z_{850} \lesssim 25.8 \) mag, and have visually inspected each one of their spectra for the presence of intervening absorption lines, finding none. Based on the S/N of the spectra, however, we estimate that we would have identified absorption features comparable to the ones we found in the GOODS LBG spectra (if they were there) only in galaxies with \( z_{850} \lesssim 25 \) mag, namely, 84 out of 92 (the GMASS spectra are significantly deeper than the GOODS ones). We have subsequently co-added the spectra of the 92 galaxies in the observed frame with no registration to any common wavelength, with the idea that if there is an Mg ii trough at \( z \approx 1.61 \) in correspondence with the overdensity, this should give rise to an

---

**Figure 4.** Distribution of the wavelength of the centroid of the line (solid histogram, bottom abscissa) and of the equivalent width (dotted histogram, top abscissa) of 5000 random realizations of the four intervening absorption features in the spectra of the three LBGs G1, G2, and G3 (G2 has two absorption features). The random realizations are obtained by varying the pixels in the spectral range \( 2705 \, \text{Å} \leq \lambda \leq 2895 \, \text{Å} \) of each spectrum by a Gaussian variate with null mean and variance equal to that spectrum’s error array.

**Figure 5.** Distribution of the equivalent width of the stack of the 5000 random realizations of the four intervening absorption features described in Figure 4 (see also the text).
absorption feature in the combined spectrum approximately at the wavelength $\lambda \approx 2.61 \times 2800$ Å, even if absorption features in the spectra of the individual galaxies might not have sufficient S/N for detection. Figure 6 shows the stacked spectrum (average top; median bottom), which has the equivalent of 2070.5 hr of integration time, plotted together with the redshift histogram of galaxies (GOODS and GMASS) in the field. We have obtained stacks with and without scaling each individual spectrum and found the results to be insensitive to the weighting scheme.

The figure shows that the peak redshift of the $z \approx 1.61$ overdensity coincides with a well-detected absorption feature in the co-added spectrum, marked by a short vertical segment (right segment). The feature is present in both the mean spectrum and in the median one, suggesting that it is not due to a few galaxies but rather is representative of the average. The area of the absorption feature and its equivalent width are $\approx 10$ times larger than those of the weakest features in its proximity (regardless of whether these weak features are noise or signal in this very deep spectrum), while its width, FWHM $\approx 23$ Å, or $\approx 950$ km s$^{-1}$, is $\approx 5$ times larger. The central wavelength of the feature is $\lambda_{c} = 7318 \pm 1$ Å, corresponding to Mg $\text{II}$ $\lambda 2800$ observed at $z = 1.65$. Another weaker feature also seems detected at $\lambda_{c} = 7285.33$ Å (left short vertical segment), at velocity separation $\Delta V = -1351$ km s$^{-1}$ from the first. The central wavelengths of the four Mg $\text{II}$ absorption features in the LBG spectra are marked with vertical dashed lines and labeled with the name of the galaxies. Additional weak absorption features are observed in the stacked spectrum at the wavelengths expected for Mg $\text{II}$ at the redshifts of two of them, namely, G2$_1$ at $z = 1.595$ and G2$_2$ at $z = 1.625$, both observed in the spectrum of G2. Since none of these absorption features are detected in the individual spectra of the background galaxies, it is difficult to constrain the strength of the absorption systems from the equivalent width in the stacked spectrum, because we do not know how many and how much galaxies contribute to the absorption.

The displacement of these possible discrete absorption features by $\approx \pm 10^{3}$ km s$^{-1}$ from the strong absorption feature in correspondence with the peak of the overdensity redshift distribution bears a striking similarity with the velocity difference of four LBG Mg $\text{II}$ absorption systems from the same redshift. We wonder if the fact that we have not found strong Mg $\text{II}$ absorption in individual spectra at the peak redshift of the overdensity is indication of some physical mechanism that reduces the covering factor of dense gas clouds inside the overdensity itself. While we cannot address this issue here, we note that the broad absorption feature of the GMASS co-added spectrum at the overdensity redshift peak would tend to prevent detection of weak, discrete absorptions at that redshift.

In any case, the existence of discrete absorption lines, including those in the LBG spectra, together with the broad one in the co-added spectrum would imply that the spatial distribution of the gas is patchy, with denser clouds embedded in a more diffuse distribution, and consistent with a relatively smaller covering factor for the high-column-density gas (e.g., atomic hydrogen column density $N_{\text{H}} \gtrsim 10^{19.2}$ cm$^{-2}$; see below). The velocity width of the $z \approx 1.61$ Mg $\text{II}$ main absorption feature, $\sigma \approx$ FWHM/2.35 = 400 km s$^{-1}$, in the stacked spectrum is comparable to the redshift width of the overdensity, $z_{\text{ms}} = 0.0383$ or $\approx 440$ km s$^{-1}$, suggesting that the kinematical broadening due to the motion of the gas is significantly less. More generally, the equivalent width of strong, saturated lines such as, very likely, the four LBG Mg $\text{II}$ absorption systems and those in the co-added spectrum, has a very weak dependence on the column density of the absorbing trough, while it gives an approximate indication of the velocity spread along the LOS. In the low S/N spectra of the four LBG Mg $\text{II}$ absorbers the line width shows that the absorbing gas has a velocity spread that is, crudely, less than a few hundred km s$^{-1}$ along the LOS, consistent with the kinematics inferred from the absorption feature in the co-added spectrum.

Finally, we also note that a number of other absorption features in the stacked spectrum are observed at the wavelengths of Mg $\text{II}$ absorption lines at the redshifts of many of the peaks of the galaxy redshift distribution. We will present further analysis of this composite spectrum (as well as other ones) in a separate work.

On the left of Figure 6, two solid vertical lines mark the expected position of the Fe $\gamma$ $\lambda 2587$ and Fe $\gamma$ $\lambda 2600$ absorption lines at the same redshift of the Mg $\text{II}$ absorption feature. There is no detected absorption in the composite spectrum at the expected central wavelength of the Fe lines that is as strong as the Mg $\text{II}$ absorption, suggesting that the contribution to the latter by the intergalactic medium (IGM) of individual galaxies is negligible. One weak feature is observed at $\Delta V \approx -190$ km s$^{-1}$ from the expected wavelength of Fe $\gamma$ $\lambda 2587$, but none is present at
the wavelength of Fe II λ2600, with the closest feature being observed at ≈+430 km s$^{-1}$ from it. We emphasize that the lack of detection of the λ2600 feature is even more significant than that of the λ2587 one, since it is stronger (stronger oscillator strength). Finally, the fact that two observed absorption features both coincide with spikes in the galaxy redshift distribution at $z \approx 1.4$ suggests that they are related to Mg ii gas associated with those overdensities, and not to Fe ii gas associated with the $z \approx 1.61$ one.

In conclusion, the analysis of the GMASS composite spectrum of galaxies at $z > 1.65$, i.e., in the background of the overdensity, provides additional, independent evidence of absorption by an Mg ii trough associated with the $z \approx 1.61$ galaxy overdensity whose chemical enrichment in terms of the Fe and Mg relative abundance is qualitatively similar to that observed in the four LBG absorption systems. There is also evidence that the typical velocity fields of the gas within the overdensity is a few $10^2$ km s$^{-1}$ and that the spatial distribution of the gas is patchy and consistent with high-column-density clouds having a relatively small covering factor.

Figures 7 and 8 show the position on the plane of the sky of the galaxies from the GOODS and GMASS spectroscopic samples, plotted together with surface density contours of galaxies with photometric redshift in the range $1.56 < z_{\text{phot}} < 1.64$, i.e., candidate members of the $z \sim 1.6$ overdensity. To assess the robustness of the photometric redshifts tracing large-scale structures, we used two independent photo-z catalogs in the GOODS-S field, one made by Dahlen et al. (2010) and the other by Y. Guo et al. (2011, in preparation; see also Guo et al. 2011 and Cassata et al. 2010 for a brief description of this catalog); both take advantage of the 12 band GOODS panchromatic photometric catalog (UBVizJHK plus the four IRAC bands at 3.6, 4.5, 5.8, and 8.0 μm). As the figures show, most of the large density peaks are observed at the same position in both catalogs, although the morphology of the regions with lower density contrast varies between the two catalogs. In particular, galaxy G1 is in the background of a relatively overdense region in Figure 7, and of an underdense one in Figure 8. As noted before, galaxies G1, G2, and G3 are approximately aligned along a line and are on the outside of the region where most of the GMASS spectroscopically identified galaxies, either belonging to the overdensity or in the background, are located. The spatial extension of the overdensity, however, seems to be much larger than this region, covering at least all of the extent of the GOODS field, approximately 10 arcmin × 16 arcmin, or 13.3 Mpc × 21.2 Mpc at $z = 1.61$ (comoving), and perhaps more.
In summary, from intervening Mg\textsc{ii} λλ2797, 2803 absorption features in the spectra of three LBGs at 3 < z < 3.5 and in the average stacked spectrum of 92 galaxies at z > 1.65 (not including the LBG) we have identified gas apparently associated with a large overdensity of galaxies at z ≈ 1.61, whose spatial distribution extends at least over the same projected linear size of the overdensity, namely ≳ 10 Mpc, and with a likely patchy distribution of column density. From both the spectra of the LBG and that of the 92 z > 1.65 galaxies there is no evidence of corresponding Fe\textsc{ii} absorption, a feature that has approximately equal strength in the spectra of the outflows from star-forming galaxies at similar redshift, including the galaxies in the overdensity, suggesting that the “intra-overdensity” gas is chemically more primitive than that of the galaxies’ ISM, as we shall discuss below.

4. THE NATURE OF THE FOUR LBG ABSORPTION SYSTEMS

The top panel of Figure 9 shows the redshift of the four LBG intervening Mg\textsc{ii} absorption systems as well as the redshift distribution of galaxies in the field. It is clear that the four Mg\textsc{ii} absorbers are all located in the tails of the overdensity. Two factors likely contribute to the fact that the redshift of the absorbers apparently “avoid” those of most galaxies in the overdensity. The first is a selection effect introduced by the band of night-sky emission lines at 7200 Å ≲ λ ≲ 7400 Å, the spectral region where Mg\textsc{ii} falls for most galaxies in the overdensity. These lines bias the observations against the detection of absorption features in relatively faint spectra, such as our sample of LBG (note that the absorber of G1 and the first absorber of G2 are observed to the blue of the sky-line band, while the second absorber of G2 and that of G3 are observed at the wavelength of the weaker lines of the band). The second factor is the relatively limited size of the sample of background galaxies that are available to us, which include the 21 GOODS galaxies and the 84 GMASS ones that have adequate S/N for detection of intervening absorption systems. Hints of the presence of discrete features to the blue and to the red of the redshift distribution peak are also present in the co-added spectrum of the GMASS galaxies in the background of the overdensity shown in Figure 6, as we have observed in the previous section. In that spectrum, no discrete features can be detected in the proximity of the peak, however, because of the presence of broad absorption lines. Thus, while it is possible that some physical reasons might be responsible for the lack of discrete absorption features at small velocity separation from the peak of the galaxy redshift distribution, our current data do not allow us to address the issue at this time.

10 We note that the Kurk et al. (2009) suggest the presence of sub-structure within the overdensity, with one smaller group of galaxies centered around redshift z = 1.59 and a larger one at z = 1.61, corresponding to a velocity separation Δv ≈ 2300 km s\textsuperscript{-1}. 
The bottom panel of Figure 9 shows the shortest and second-shortest impact parameter from the LOS of each absorber, to that of the whole (GOODS and GMASS) spectroscopic sample as a function of velocity separation. These galaxies have been selected from the GOODS/Spitzer 4.5 μm images to satisfy the flux limit $m_{4.5,\text{Spitzer}} \lesssim 23$ mag, essentially a mass-limit selection criterion approximately corresponding to $m_{\text{star}} < 2 \times 10^9 M_\odot$, with a small dependence on the spectral type. There is no evidence that the absorbers are associated with any known bright galaxy in the field.

(A color version of this figure is available in the online journal.)

Figure 9. Top: histogram of known spectroscopic redshifts (top scale) and velocity difference from the median redshift, $\langle z \rangle = 1.609$ (bottom scale), of galaxies in, or in the proximity of, the $z \approx 1.6$ overdensity, together with the redshift of the central wavelength of the four Mg ii absorbers. Bottom: the projected distance at $z = 1.609$ between the LOS from each Mg ii absorber, color-coded as the top figure, to the nearest (solid circles) and second nearest (open circles) galaxies with known spectroscopic redshift as a function of velocity separation. These galaxies have been selected from the GOODS/Spitzer 4.5 μm images to satisfy the flux limit $m_{4.5,\text{Spitzer}} \lesssim 23$ mag, essentially a mass-limit selection criterion approximately corresponding to $m_{\text{star}} < 2 \times 10^9 M_\odot$, with a small dependence on the spectral type. There is no evidence that the absorbers are associated with any known bright galaxy in the field.

(A color version of this figure is available in the online journal.)

mass sensitivity (see Table 1) significantly smaller than that of galaxies thought to be capable of producing ultra-strong Mg ii absorption systems, as we shall discuss below. Figures 10, 11, and 12 show the images of the regions around the three LBGs. In each case the LBG is at the center of the concentric circles, which have a radius of 10, 50, and 100 kpc at $z = 1.6$ (1.18, 5.9, and 11.8 arcsec, respectively). Galaxies with photometric redshift in the range $1.5 < z_p < 1.7$ in either Dahlen’s or Guo’s photo-z catalog are also shown at the center of 10 kpc circles with their GOODS v2.0 ID labeled. Table 1 summarizes relevant properties of these galaxies.

The three LBGs are not detected in the $U$-band images, since these probe the spectral energy distribution (SED) beyond their Lyman limit (they have been selected as $B$-band dropouts). This is very useful, because it gives us unrestricted visibility at $z \approx 1.61$, down to the sensitivity limit of the image, to check the possible presence of faint galaxies, undetected at redder wavelengths because of overlapping with the isophotal area of the LBG, which could be responsible for the Mg ii absorption. We found that, in all cases, no source is detected in the $U$ band at the positions of the LBG down to $\approx 30$ mag arcsec$^{-2}$ 1σ surface brightness limit (Nonino et al. 2009).

In the case of G1 there are no galaxies in the $1.5 < z_p < 1.7$ range with impact parameter closer than 10 kpc, at the redshift of the Mg ii absorption system, from the LOS to the LBG. The closest galaxy to G1, which has photometric redshift $z \approx 3.5$ and is also undetected in the $U$ (it is barely detected in the $z_{850}$ band, but clearly visible in the $R$ one), is very likely a companion of the LBG itself. There is a very faint galaxy within the 50 kpc radius, ID = 10419, with $z_{850} = 27.20$ mag which, if located at the redshift of the absorber, would correspond to...
rest-frame 3300 Å absolute magnitude $M_{3300} = -17.1$. In Guo et al.'s catalog this galaxy has peak and weighted photometric redshift $z_p = 1.69$ and $z_w = 1.4589$, respectively, and stellar mass $\log(M) = 8.4$. Another two faint galaxies, ID = 10520 with $z_{850} = 27.13$ mag and ID = 10479 with $z_{850} = 26.48$ mag, are located in close proximity of the 50 kpc radius; the former barely enters in the selected photo-$z$ window, while for the latter the two measures of the photo-$z$ are widely discrepant. As we shall discuss in the next section, none of the galaxies around G1 is a good candidate for being the host of the Mg II absorbing trough.

Galaxy G2 has one galaxy within the 10 kpc circle and two galaxies inside the 50 kpc circle, which all have high photometric redshifts ($z > 3$), are undetected in the $U$ band and, thus, are likely spatially associated with it. The only galaxy inside the 50 kpc circle with $1.5 < z < 1.7$, ID = 14131, has $z_{850} = 25.5$ mag and stellar mass $\log(M) = 9.12$. As we will see below, its mass seems too small by at least one order of magnitude to be able to host an ultra-strong absorber, given the impact parameter. Also, even if this galaxy were responsible for one of the two absorption systems of G2, it would be very unlikely causing the other one, given the large velocity separation between them. The fact that the second absorber would then remain without a galaxy identification argues in favor of the interpretation that these LBG absorption systems are not caused by gas associated with individual galaxies.

Galaxy G3 has two galaxies around it with relatively small impact parameters, one just outside the 10 kpc circle (ID = 14876) and the other at about 25 kpc (ID = 14871). The former has $z_{850} = 26.0$ mag, $K_s = 25.0$ mag, and $\log(M) = 9.0$, the latter $z_{850} = 27.7$ mag, $K_s = 29$ mag, and $\log(M) = 7.8$. Again, as it will be clearer in the next section, both galaxies seem too small and faint to qualify as likely candidate hosts of the absorbing trough.

Finally, we note that while there is no strong bias against early-type galaxies in the GMASS flux limit selection criterion, the spectroscopic identification of these galaxies requires substantially higher sensitivity than star-forming galaxies with the
The Astrophysical Journal, 743:95 (24pp), 2011 December 10

Giavalisco et al.

Figure 11. As in Figure 10, but for galaxy G2. The three unmarked galaxies between the 10 and 50 kpc circles and the one on the 50 kpc circle to the ENE of the LBG are very likely at redshift \( z > 3 \) as shown by their colors (all are \( U \)-band dropouts).

(A color version of this figure is available in the online journal.)

same \( m_{4.5, \mu m} \) apparent magnitude because of the lack of emission lines in their spectra. As a result, it is possible that, using only the spectroscopic sample, massive and passively evolving galaxies at \( z \sim 1.61 \) located in close proximity to the LOS to the four LBGs, and thus potentially capable to host gas responsible for the absorption systems, might have eluded identification. There is no evidence of the presence of such galaxies around G1, G2, or G3 based on the deep \( URz \) images discussed here.

5. THE NATURE OF THE ABSORBING GAS

The properties of the gas responsible for optically thick Mg\( \, \text{II} \) QSO intervening absorption systems, and for the strong interstellar absorption in the outflows of starburst galaxies, provide a very useful reference to infer the nature of the gas responsible for our LBG Mg\( \, \text{II} \) absorption systems, as well as the Mg\( \, \text{II} \) absorption observed in the co-added GOODS and GMASS spectra.

5.1. Gas Responsible for QSO Mg\( \, \text{II} \) Intervening Absorption Systems

A vast body of work on QSO absorption systems has characterized the properties of the gas capable to give rise to strong intervening Mg\( \, \text{II} \) absorption features observed in their spectra. The main results that concerns this work is that this low-ionization species is a tracer of a warm medium, \( T \sim 10^4 \text{ K} \), associated with atomic hydrogen, and that strong Mg\( \, \text{II} \) absorption systems, traditionally defined as those observed with rest-frame equivalent width \( W_r > 0.3 \text{ Å} \), originate in optically thick H\( \text{I} \) gas having column density \( N_{\text{H}1} > 10^{17} \text{ cm}^{-2} \). It must be emphasized that this is a lower limit to the column density of atomic hydrogen; it is very likely that the column density of the H\( \text{I} \) gas responsible for strong Mg\( \, \text{II} \) absorption is much higher than this value (see Steidel & Sargent 1992). At relatively low redshift (e.g., \( z \lesssim 1.5 \)) a key property of strong Mg\( \, \text{II} \) absorption systems is that the gas responsible for them is often found to be part of the extended gaseous halos around massive, bright galaxies, roughly with \( L/L^* > 0.3 \) and \( M > 3 \times 10^{10} M_{\odot} \), with little or no dependence on the spectral and morphological type (e.g., Steidel et al. 1997, 2002; Churchill et al. 2007). Chen et al. (2010) find that the extent of the Mg\( \, \text{II} \) absorbing gas around galaxies depends strongly on their stellar mass \( M_{\text{star}} \) and more weakly on the specific star formation rate (SSFR), and suggest that this is naturally explained if gas exchange to and from galaxies, i.e., outflows and inflows, are the mechanisms that provide the gas responsible for the absorption.

\[ \text{same } m_{4.5, \mu m} \text{ apparent magnitude because of the lack of emission lines in their spectra. As a result, it is possible that, using only the spectroscopic sample, massive and passively evolving galaxies at } z \sim 1.61 \text{ located in close proximity to the LOS to the four LBGs, and thus potentially capable to host gas responsible for the absorption systems, might have eluded identification. There is no evidence of the presence of such galaxies around G1, G2, or G3 based on the deep } URz \text{ images discussed here.} \]

\[ \text{5. THE NATURE OF THE ABSORBING GAS} \]

\[ \text{The properties of the gas responsible for optically thick Mg\( \, \text{II} \) QSO intervening absorption systems, and for the strong interstellar absorption in the outflows of starburst galaxies, provide a very useful reference to infer the nature of the gas responsible for our LBG Mg\( \, \text{II} \) absorption systems, as well as the Mg\( \, \text{II} \) absorption observed in the co-added GOODS and GMASS spectra.} \]

\[ \text{5.1. Gas Responsible for QSO Mg\( \, \text{II} \) Intervening Absorption Systems} \]

\[ \text{A vast body of work on QSO absorption systems has characterized the properties of the gas capable to give rise to strong intervening Mg\( \, \text{II} \) absorption features observed in their spectra. The main results that concerns this work is that this low-ionization species is a tracer of a warm medium, } T \sim 10^4 \text{ K}, \text{ associated with atomic hydrogen, and that strong Mg\( \, \text{II} \) absorption systems, traditionally defined as those observed with rest-frame equivalent width } W_r > 0.3 \text{ Å}, \text{ originate in optically thick H\( \text{I} \) gas having column density } N_{\text{H}1} > 10^{17} \text{ cm}^{-2}. \text{ It must be emphasized that this is a lower limit to the column density of atomic hydrogen; it is very likely that the column density of the H\( \text{I} \) gas responsible for strong Mg\( \, \text{II} \) absorption is much higher than this value (see Steidel & Sargent 1992). At relatively low redshift (e.g., } z \lesssim 1.5 \text{) a key property of strong Mg\( \, \text{II} \) absorption systems is that the gas responsible for them is often found to be part of the extended gaseous halos around massive, bright galaxies, roughly with } L/L^* > 0.3 \text{ and } M > 3 \times 10^{10} M_{\odot}, \text{ with little or no dependence on the spectral and morphological type (e.g., Steidel et al. 1997, 2002; Churchill et al. 2007). Chen et al. (2010) find that the extent of the Mg\( \, \text{II} \) absorbing gas around galaxies depends strongly on their stellar mass } M_{\text{star}} \text{ and more weakly on the specific star formation rate (SSFR), and suggest that this is naturally explained if gas exchange to and from galaxies, i.e., outflows and inflows, are the mechanisms that provide the gas responsible for the absorption.} \]
The distribution of impact parameters, i.e., the distance from the line sight to the QSO (the location of the absorbing clouds) to the center of the gas host galaxies, for strong Mg II absorption to take place has been found to be in the range 15 kpc \( d \lessgtr 80 \) kpc, with covering factor in the range 0.5 \( C_F \lessgtr 1 \), depending on how the sight line to the QSO is selected. For example, if Mg II gas is known to be present at a particular redshift because of the strong absorption system observed in a QSO’s spectrum, then there is a very high probability (\( \sim 100\% \)) that a bright galaxy will be found nearby the LOS to the QSO as the likely host of the gas (Steidel et al. 1994). The converse case does not seem to be true. Namely, the spectra of QSOs whose LOS has impact parameter to a known bright galaxy in the above range have been observed to have strong intervening Mg II absorption systems at the redshift of the galaxy only roughly \( \sim 50\% \) of the time (Tripp & Bowen 2005). Recently, Gauthier et al. (2009, 2010) and Bowen & Chelouche (2011) found evidence that the covering factor around the so-called Luminous Red Galaxies at \( z \sim 0.5 \), essentially galaxies photometrically selected for having very low SSFR (passively evolving), is significantly smaller, \( C_F \sim 10\%–15\% \). They suggest that either the halos of these galaxies are too hot to retain or accreted cold gas, or these passively evolving galaxies simply do not have the cool (i.e., \( T \sim 10^4 \) K) outflows to fill their halos with Mg II absorbing clouds.

Ultra-strong absorbers, i.e., \( W_r > 3 \) Å, have also been observed in the spectra of QSOs, as well as star-forming galaxies where the gas is back illuminated by the galaxies’ own UV light (Nestor et al. 2005, 2007; Tremonti et al. 2007). They are between two and three orders of magnitude rarer than weaker ones. These are generated by gas that resides either inside the galaxies or in the outflows ejected from starburst ones. Nestor et al. find that ultra-strong Mg II absorption systems can also be caused by gas in dwarf galaxies that are aligned along the LOS to the QSO, i.e., with the LOS intersecting their optical light profile. In other words, to have sufficient column density to give rise to ultra-strong absorption, the gas hosted by dwarf galaxies needs to be located at very small impact parameter (less than a few kpc).

Nestor et al. (2005) and Rao et al. (2006) find evidence that a substantial fraction of ultra-strong absorbers, perhaps \( \gtrsim 65\% \), are also damped Ly\( \alpha \) (DLA) absorbers, implying that the H I gas column density exceeds the value \( N_{\text{HI}} > 2 \times 10^{20} \) cm\(^{-2} \). Conversely, every DLA is also an Mg II absorber (e.g., Rao et al.

Figure 12. As in Figures 10 and 11, but for galaxy G3. All the unmarked galaxies inside the 50 kpc circle, even if they had redshift \( z \sim 1.61 \), are too faint to be responsible for the ultra-strong Mg II absorption feature in the spectrum of G3 (see the text). (A color version of this figure is available in the online journal.)
Although Mg II absorption can be generated by gas with column density up to ~3 orders of magnitude smaller than that of DLA, e.g., \(N_{\text{H}} > 10^{17}\) for \(W_r > 0.3\) \(\text{Å}\), at least the most metal-rich DLA have Mg II absorption with equivalent width in the range \(2 \lesssim W_r \lesssim 3\) \(\text{Å}\) (see Nestor et al. 2007), and as many as \(\approx 90\%\) of all DLA have \(W_r \lesssim 3\) \(\text{Å}\), Rubin et al. (2010b) find that ultra-strong Mg II absorbers \((W_r > 2.72\) \(\text{Å}\) in their sample) produced in the outflows from star-forming galaxies at \(0.7 < z < 1.5\), which have stellar mass and star formation rate in the same range as the galaxies in our GOODS and GMASS samples (see their Figure 8 and Kurk et al. 2009), have atomic hydrogen column density \(N_{\text{H}} \gtrsim 10^{19.2}\) \(\text{cm}^{-2}\). Note that the equivalent width of these absorbers is smaller than the average equivalent width of our four Mg II LBG absorption systems (both components of the doublet), namely \(W_r = 6.3 \pm 1.5\) \(\text{Å}\); the smallest equivalent width among the four of them, one of the two in G2’s spectrum, has \(W_r = 5.4 \pm 2\) \(\text{Å}\). It is also smaller or comparable to the equivalent width of the individual components of the doublet estimated above.

Cases of optically thick absorption systems (not necessarily Mg II systems) that are at least strong, i.e., \(W_r > 0.3\) \(\text{Å}\), for which an association with an individual bright galaxy could not be made are rather rare. Examples include Tripp et al. (2005), who reported a sub-DLA absorber with \(N_{\text{H}} = 10^{19.32}\) and remarkably low metallicity \((\text{O}/\text{H}) = -1.60\) for which no galaxy could plausibly provide the gas to explain the absorption (the nearest galaxy is a sub-\(L^*\) galaxy with impact parameter \(d = 86\) \(\text{kpc}\), while the closest \(L^*\) galaxy has \(d = 246\) \(\text{kpc}\)); and Fumagalli et al. (2010), who looked for the galaxies responsible for two QSO DLA by imaging the area around the QSO at wavelengths below its Lyman limit, so that the QSO’s light is suppressed, offering unrestricted visibility along the LOS, and for one case they found no galaxy host.

In summary, the conclusion from all these works is that strong and ultra-strong Mg II absorption systems \((W_r > 0.3\) \(\text{Å}\)) require large H I column density, especially ultra-strong absorbers, whose column density reaches the threshold value required for DLA. These conditions are thought to be encountered in the gas flows that are being exchanged to and from massive galaxies, either outflows, which are commonly observed in star-forming galaxies at high redshift, or inflows, for which there has been no direct evidence so far. In the case of the outflows, their large spatial extent, physical conditions, and geometry naturally explain many of the observed properties of the absorbers, including the proximity of the LOS to a bright galaxy \((d < 100\) \(\text{kpc}\)) and the inverse correlation between equivalent width and impact parameters (see Steidel et al. 2010). The case for the inflow is much less clear. The gas is expected to come from large separations from the galaxies, along what the theory predicts to be filamentary streams. Thus, a high column density does not necessarily require spatial proximity to a bright galaxy. The overall covering factor is expected to be fairly small, however, revised to \(\lesssim 3\%\) around a \(10^{12}\) \(\text{M}_\odot\) halo (Kimm et al. 2010; A. Dekel 2010, private communication) from early estimates of \(\approx 20\%\)–\(25\%\) (Dekel et al. 2009a, 2009b). This is consistent with the paucity of inflow kinematic signature in most absorbers, as well as with the rarity of absorbers with no galaxies responsible for them.

The equivalent width of our four “LBG” Mg II systems qualifies them as ultra-strong absorbers; however, different from most “QSO” Mg II absorption systems, intervening bright galaxies do not appear to be directly responsible for them, as we have seen in Section 4. Also, note that given the relatively low S/N of our spectra, we cannot detect absorption lines significantly weaker than ultra-strong. Thus, from the spectra of our galaxies we do not have information on the presence and/or location of gas capable of generating weaker absorption.

Finally, we conclude with a crude estimate of the mass of the H I gas associated with the absorbing trough observed in the LBG spectra, as well as of the mass associated with the overdensity as a whole. Indeed, the resolved nature of galaxies as probes of absorption systems lends itself to some interesting inferences on the properties of the trough, such as a lower limit to the mass of the gas. The large equivalent width of the four absorption features and their minimum light intensity consistent with zero indicate that the absorbing gas covers the full angular extent of the LBG. Hence, making an educated assumption on the average H I column density associated with the Mg II gas based on the known properties of similar Mg II absorbers that we have discussed, a lower limit to the mass of the H I gas clouds is

\[
M_c \approx 2.5 \times 10^6 \times \left( \frac{N_{\text{H}}}{10^{19} \text{cm}^{-2}} \right) \times \left( \frac{D}{10\text{kpc}} \right)^2 \text{M}_\odot.
\]

where \(D\) is the physical size at \(z \approx 1.61\) subtended by the angular diameter of an LBG at \(z \approx 3\), i.e., the optically bright (rest UV) part of the galaxy that mostly contributes to the observed spectra, which is typically \(5\)–\(7\) \(\text{kpc}\) (Giavalisco et al. 1996; Ferguson et al. 2004; Ravindranath et al. 2006). The absorber’s H I mass, however, is almost certainly larger, since it is very unlikely that it has the same angular extent of the LBG.

In turn, a crude lower limit to the total mass of the gas can be derived from the linear extent \(R\) of the overdensity, a few Mpc, and the covering factor of the high-column-density gas, \(C_f \approx 4/105 = 0.04\), namely, the ratio of the number of observed absorbers (4) to the total number of spectra analyzed and potentially of sufficient quality to reveal the presence of ultra-strong absorption systems \((21+84 = 105)\). We find

\[
M_T > 10^{13} \times \left( \frac{C_f}{0.04} \right) \times \left( \frac{M_c}{2.5 \times 10^6 \text{M}_\odot} \right) \times \left( \frac{R}{2\text{Mpc}} \right)^2 \left( \frac{D}{10\text{kpc}} \right)^2 \text{M}_\odot.
\]

5.2. The Metal Enrichment of the z \(\approx 1.61\) “Intra-overdensity” Gas

The lack of the Fe II interstellar absorption lines, which generally have strength similar to the Mg II ones in star-forming galaxies (see Leitherer et al. 2011; Rubin et al. 2010a, 2010b; see also Nestor et al. 2011 and Tremonti et al. 2007), in both the stacked spectrum of the four LBG absorption systems (Figure 3, top) and in the GMASS stack of the \(z > 1.65\) background galaxies (Figure 6), is the key piece of evidence that the “intra-overdensity” gas is not directly associated with, and is chemically older than, the ISM and/or the outflows of galaxies in the overdensity.

In principle, the underabundance of Fe II could be due to depletion of Fe by dust. While both iron and magnesium are prone to dust depletion, in cold (e.g., \(T < 10^5\) K) and dense gas Fe can be significantly more depleted than Mg (Savage & Sembach 1996). The physical conditions for preferential depletion of Fe over Mg could be encountered in the ISM in galactic disks. However, the lack of massive, luminous galaxies \((L/L^* \gtrsim 0.3\) and \(M \gtrsim 10^{10} \text{M}_\odot\)) at \(z \approx 1.61\) with
likely that the absorption arises in the space between galaxies, redshift) are not sufficiently massive. In this situation it is more qualify as potential absorbers (assuming they have the right impact parameter would be in the plausible range to give rise to the absorption). Small ($d < 100$ kpc) impact parameter from the LOS to the absorbers argues against this interpretation. The few galaxies whose impact parameter would be in the plausible range to qualify as potential absorbers (assuming they have the right redshift) are not sufficiently massive. In this situation it is more likely that the absorption arises in the space between galaxies, at large impact parameter ($d > 100$ kpc) from any bright one or around the overdensity as a whole. In both cases the gas is likely to have temperature $T \sim 10^4$ K due to photoionization heating from the UV background and density similar to that of other ultra-strong Mg II absorbers, such as the gas in the outflows (see Steidel et al. 2010). In these physical conditions, the relative depletion of Mg and Fe should be similar. Moreover, such regions (i.e., low-density outer gaseous halos of galaxies or intergalactic gas clouds) generally contain little dust (e.g., Tripp et al. 2002, 2005). A more likely explanation, therefore, is that the Fe underabundance reflects the nucleosynthetic history of the gas. Magnesium is an $\alpha$-element that is rapidly produced in Type II supernovae (SNe), while Fe is more slowly produced in Type Ia SNe, so Fe can be underabundant compared to Mg (e.g., McWilliam 1997). This suggests that the absorbing gas is relatively “chemically young,” or at least younger than the gas in galactic outflows. The S/N and spectral resolution of the stacked spectrum are not adequate to support a detailed quantitative analysis, but the redshift is high enough to bring a number of additional metal lines into the optical band, so future follow-up studies will be valuable for constraining the nature of the absorbing gas.

To compare the chemical composition of our “intra-overdensity” gas to that of the ISM of galaxies we need to translate the observed equivalent width ratio into an abundance ratio. Unfortunately, this is not possible, because the lines are almost certainly saturated, and thus the equivalent width is not a tracer of the gas column density. In addition, we also lack the knowledge of the H I column density, as well as of the ionization correction. Since no absorption by Fe is detected, however, and since in saturated lines the column density is underestimated, the ratio of the equivalent widths of Fe II to Mg II provides a crude limit to the elemental abundance ratio, if both species are contained in the same gas and partake of the same kinematics:

$$\frac{\text{Mg II}}{\text{Fe II}} > \log \left( \frac{W_{\text{Mg II}}}{W_{\text{Fe II}}} \right) \approx \log \left( \frac{6.3}{1.5} \right) = 0.623.$$  

We can then compare this lower limit to measures of the abundance ratio of $\alpha$-elements to iron-peak in galaxies, and in particular to bright ellipticals, since these systems are more enriched in magnesium relative to iron than other galaxy types (see, e.g., Thomas et al. 2010; Jorgensen 1997; Worthey et al. 1992). Figure 13 shows the distribution of $[\alpha/\text{Fe}]$ for early-type galaxies with velocity dispersions of $27$ km s$^{-1} < \sigma < 80$ km s$^{-1}$ (red histogram; Sansom & Northeast 2008) and $50$ km s$^{-1} < \sigma < 360$ km s$^{-1}$ (black histogram; Thomas et al. 2005) and the lower limit to the abundance ratio of Mg and Fe in our gas estimated above. As the figure shows, the chemical enrichment pattern of our gas appears to significantly differ from that observed in the galaxies. Stars in the halo of the Milky Way also have $\alpha$-elements enhanced relative to iron (see Wheeler et al. 1989). Bonifacio et al. (2009) find that the most metal-poor stars in the halo of the Milky Way have $[\alpha/\text{Fe}] \lesssim 0.8$ (see their Figure 4), which provides an estimate of the elemental ratio in nucleosynthesis products by Type II SNe. Clearly, being able to measure $[\alpha/\text{Fe}]$ for our gas in future spectra with higher S/N will be invaluable to constrain its nature and the nucleosynthetic history.

We have further investigated the Mg and Fe elemental ratio of the gas using version 8.00 of the photoionization code CLOUDY (Ferland et al. 1998) to calculate the column density ratio of Mg II to Fe II if photoionized by the metagalactic far-UV background. This is illustrated in Figure 14, where the column density ratio is plotted as a function of the ionization parameter given the QSO spectrum of Haardt & Madau (1996), assuming one-tenth solar metallicity for the gas chemical abundance and
using the solar elemental ratio of $\alpha/\text{Fe}$ by Asplund et al. (2009) for three assumed values of the H I column density. We have also repeated the calculation using the QSO+galaxy version of the Haardt & Madau spectrum, finding very similar results. The top abscissa in the figure shows the value of the H I volume density, in cm$^{-3}$, corresponding to the ionization parameter for the case of column density $N_{\text{HI}} = 2 \times 10^{20}$ cm$^{-2}$. As the curves show, if the H I column density is sufficiently high, e.g., like that of DLAs, most of the gas cloud is shielded from the ionizing effects of the external radiation, and the column density ratio of Mg $\text{II}$ and Fe $\text{II}$ remains approximately constant over a relatively large range of the ionization parameter (this ratio can actually be lower than the solar value in this case because some of the Mg is in the form of Mg $\text{I}$). For significantly lower column density, e.g., similar to and lower than that of Lyman Limit Systems, $2 \times 10^{20}$ cm$^{-2}$, then the outer regions of the cloud become increasingly more ionized as the ionization parameter increases and, due to the differences in their ionization potential, Mg $\text{II}/\text{Fe II}$ increases with it. The conclusion of this calculation is that if the column density of the gas is indeed as high as we have argued above, then the observed strength of the Mg $\text{II}$ and Fe $\text{II}$ absorption features is expected to be similar, if their elemental ratio is similar to solar, and similar to what observed in the ISM of star-forming galaxies in the $z \sim 1.61$ overdensity. Since we do observe Mg $\text{II}$ but not Fe $\text{II}$, even if we could have observed it, either in the combined spectrum of the LBG absorption systems or in the combined spectrum of the GMASS background galaxies, the conclusion above strongly supports our interpretation that the absorbing gas is chemically younger than the ISM in galaxies. Finally, as a consistency check we have verified that if the spatial size of the absorbing cloud is of the order of $\sim 10$ kpc, i.e., the size subtended by the angular diameter of galaxies in range of redshift discussed here (e.g., see Ferguson et al. 2004), then a DLA-like column density implies H I volume density of the order of $2 \times 10^{20}$ cm$^{-2}/3.086 \times 10^{24}$ cm $= 0.065$ cm$^{-3}$, namely, in the same range of density expected given the Haardt & Madau spectrum.

5.3. Evidence of Mg $\text{II}$ Gas Accreting on Some of the Galaxies?

In Section 3 we observed that the Mg $\text{II}$ absorption line found in the co-added spectrum of the 16 GOODS galaxies belonging to the $z \sim 1.61$ overdensity (spectrum (c) of Figure 3) seems to include a broad, asymmetric “red wing” feature extending to the red of the Mg $\text{II}$ $\lambda 2803$ line, with possible additional discrete lines overimposed to it (see spectrum (c) in Figure 3). At the same time, no similar blue wing is observed in the spectrum. Such an absorption profile can result from gas along the LOS to most of the galaxies, located in relatively close spatial proximity to them, that is moving toward the galaxies or toward the overdensity as a whole, i.e., receding from the observer. This gas could also be accreting onto some of the galaxies. In view of the importance that such evidence would play in constraining the nature of the gas that we have identified in the context of cold accretion, we have further investigated this issue taking advantage of the GMASS spectroscopic sample, which is larger than our GOODS one and includes deeper spectra.

We have averaged together the GMASS rest-frame spectra of 33 galaxies belonging to the $z \approx 1.61$ overdensity ($1.56 \leq z \leq 1.64$, $z = 1.608$) to provide an independent average spectrum of galaxies in the same structure where we have detected our “pristine” Mg $\text{II}$ gas, whose equivalent exposure time of $T_{\text{exp}} = 855$ hr provides significantly higher sensitivity to gas absorption features than any individual galaxy. As a control spectrum, we have averaged together the 92 GMASS spectra of galaxies at $z > 1.65$, i.e., in the background of the overdensity this time after shifting each of them to the rest frame. It makes no difference if the spectra are scaled prior to computing the average. Whenever possible, the redshift of the galaxies is measured from the [O III] nebular emission lines, since this provides a good measure of the systemic redshift.

When [O III] is not present in the available spectral range, the redshift is estimated from the Mg $\text{II}$ and Fe $\text{II}$ absorption lines; 19 of the 33 overdensity galaxies and 1 of the background galaxies have [O III] redshift. We have also experimented with co-adding only galaxies with [O III] emission and those without, finding similar results, as we will discuss later. The 33 co-added spectra are shown in Figure 15 together with the GOODS stack of the overdensity galaxies and the stack of the $z \sim 0$ starburst galaxies, for comparison (the latter two spectra are the same as those shown in Figure 3). Figure 16 zooms in the spectral region around the Mg $\text{II}$ absorption in the GMASS and GOODS stacks and also shows the velocity difference of the absorption features relative to the rest-frame wavelength of the Mg $\text{II}$ $\lambda 2803$ line. Again, possible discrete absorption features to the red of the main interstellar absorption features are marked by vertical segments.

Like the GOODS, the GMASS stack of the $z \approx 1.61$ overdensity galaxies also shows a discrete absorption feature to the red of the Mg $\text{II}$ $\lambda 2803$ line, apparently characterized by two minima, at approximately the same wavelength as the redder feature of the two observed in the GOODS stack. In fact, the redder of the two minima, marked by the right vertical segment in Figure 16, coincides (within the resolution of the spectra) with the redder feature of the GOODS spectrum. Overall, the whole absorption feature, i.e., including the two contiguous minima, is detected at the $\gtrsim 10^\sigma$ level, similar to the Mg $\text{II}$ $\lambda 2852$ line. The GMASS stack, however, shows a relatively strong emission line (more on this later) immediately to the red of the strong interstellar Mg $\text{II}$ $\lambda 2803$ absorption line, roughly at the same wavelength of the bluer of the two discrete absorption features in the GOODS stack, as illustrated in Figures 15 and 16. Overall, although taken individually each absorption feature is detected at low level, their simultaneous presence in both the GMASS and GOODS co-added spectra and the approximated coincidence in wavelength strongly argues in favor of them being real, since the GMASS and GOODS galaxies come from two different samples and cover somewhat different regions of the GOODS-S field (see Figures 7 and 8). No similar absorption features are observed in the co-added spectrum of the 92 background galaxies at $z > 1.65$. Also, neither the two GMASS stacks nor the GOODS one shows any obvious similar absorption feature to the blue of the main Mg $\text{II}$ $\lambda 2797$ interstellar line.

All these absorption features, both the discrete ones and the broader, continuum one, must be caused by a distribution of intervening Mg $\text{II}$ clouds. An obvious interpretation for their redshift relative to the Mg $\text{II}$ doublet and for the broad profile of the broad “red wing” absorption profile is that the gas is moving toward the overdensity and/or at least some of the galaxies contributing to the two stacked spectra. An extended Mg $\text{II}$ cloud would produce the broad continuous “red wing” absorption profile observed in their co-added spectrum, while individual, denser clouds embedded in this medium would be responsible for the discrete features. The top horizontal scale in Figure 16 shows the velocity difference relative to the $\lambda 2803$ line of the Mg $\text{II}$ doublet. Thus, the implied relative velocity of the two discrete features in the GOODS stack (spectrum (c)}
Figure 15. (a) The co-added spectrum of the 33 GMASS galaxies with $1.56 \leq z \leq 1.64$ in the $z \approx 1.61$ overdensity and (b) that of the 92 GMASS galaxies at $z > 1.65$ in the background. Also plotted are (c) the co-added spectrum of the 16 GOODS overdensity galaxies and (d) that of the $z \sim 0$ starbursts, the same as those shown in Figure 3. The GOODS stack shows the possible presence of a broad “red wing” absorption feature, extending to the red of the interstellar $\text{Mg}^{\text{II}}$ absorption, with additional discrete components (marked by vertical segments) superimposed. The GMASS stack shows a discrete absorption feature at approximately the same wavelength of one of similar discrete features in the GOODS stack. The broad “red wing,” however, is not as clearly visible, mostly because of an emission line (marked by a vertical segment), immediately to the red of the interstellar $\text{Mg}^{\text{II}}$ absorption feature. This is the emission component of the $\text{Mg}^{\text{II}}$ P-Cygni feature frequently observed in star-forming galaxies at high redshift together with fine-structure emission lines of $\text{Fe}^{\text{II}}^*$ (Rubin et al. 2010a, 2010b; Weiner et al. 2009), which are indeed detected in all of our co-added spectra.

in Figure 15) would be $\approx 700$ and $\approx 1600$ km s$^{-1}$, respectively. Such values of the velocity are higher than the predictions for accretion of cold gas onto $M \sim 10^{12}$ halos, which are about 200 km s$^{-1}$, but they are at least qualitatively consistent with the average relative velocity between gas clouds and galaxies within the much more massive overdensity. We also recall, in this regard, that the redshift of the four intervening LBG absorption systems is displaced by up to $\pm 1000$ km s$^{-1}$ relative to the peak of the overdensity.

The broad “red wing” is analogous to the “blue wing” absorption profile observed immediately to the blue of the far-UV interstellar metal absorption lines discussed by Steidel et al. (2010) in the same types of galaxies. In the case of the “blue wing,” the feature originates in gas outflows from the galaxies, while the “red wing” discussed here originates in inflows. Since ultra-strong $\text{Mg}^{\text{II}}$ absorption traces hydrogen gas with $N_\text{H} \gtrsim 10^{20}$ cm$^{-2}$, we interpret the detection of the “red wing” as evidence of accretion of cold, chemically relatively young gas onto the $z \approx 1.61$ overdensity. This gas might very well feed star formation in the star-forming galaxies that belong to the overdensity, although there is no direct evidence of this fact.

The broad “red wing” is not as clearly observed in the GMASS stack of the overdensity galaxies as it is in the GOODS one because of the presence of a relatively strong emission line, which is the emission component of an $\text{Mg}^{\text{II}}$ P-Cygni feature. As noted before, Figures 15 and 16 show the presence of emission lines immediately to the red of the $\lambda = 2803$ Å component of the $\text{Mg}^{\text{II}}$ doublet. Emission of $\text{Mg}^{\text{II}}$ is very rarely seen in starburst galaxies in the local universe that have no AGN activity (e.g., Tololo 1924-416; Kinney et al. 1993), but it appears to be more common at high redshift (Weiner et al. 2009; Rubin et al. 2010a, 2010b, 2011), where the feature is observed in conjunction with emission lines by fine-structure transitions of $\text{Fe}^{\text{II}}^*$ and has a P-Cygni profile. We detect the $\text{Fe}^{\text{II}}^*$ fine-structure lines in all our co-added spectra (in fact, they are detected in the majority of the individual spectra), although they do not seem to be present in the $z \sim 0$ spectrum. While observational evidence of these lines is accumulating at high redshift (Weiner et al. 2009; Rubin et al. 2010a, 2010b; K. Kornei et al. 2011, in preparation) very little is known about the physical mechanisms that produce them. Rubin et al. (2011) and Prochaska et al. (2011) have proposed that both the $\text{Fe}^{\text{II}}^*$ fine-structure emission lines and the P-Cygni $\text{Mg}^{\text{II}}$ feature originate by photon scattering in the outflows that characterize distant star-forming galaxies (Weiner et al. 2009; Steidel et al. 2010), although these lines can also be produced in recombination regions (Kinney et al. 1993) or AGN (Vestergaard & Wilkes 2001). The $\text{Fe}^{\text{II}}^*$ lines are very well detected in two of the GMASS stacks and in the GOODS stack shown in Figure 15 (see also the stack of the GOODS spectra of the overdensity galaxies in Figure 3), where the two lines $\text{Fe}^{\text{II}}^* \lambda 2612$ and $\text{Fe}^{\text{II}}^* \lambda 2626$ are blended because of the lower spectral resolution. Interestingly, all the $\text{Fe}^{\text{II}}^*$ lines and
the MgII emission line are stronger in the GMASS stack of the 33 overdensity galaxies than in the stack of 92 background ones, despite the longer equivalent exposure time of the latter, very likely because for nearly all of the [OII] is outside the available spectral range, and thus their redshift is determined from the absorption features of FeII and MgII. Since these lines are heavily affected by the outflows, their redshift deviates from the systemic one by a random amount, between a few to several hundred km s\(^{-1}\) (Steidel et al. 2010), and thus the strength of the stack of the FeII lines, which are at the systemic (Rubin et al. 2011), is diluted. In comparison, more than half of the redshifts of the \(z \approx 1.61\) overdensity galaxies are measured from the [OIII] line.

As noted before, the FeII lines are not observed in the stacked spectrum of the \(z \approx 0\) starburst galaxies by Leitherer et al. (2011) reproduced in Figures 3 and 15. We suggest that this is due to the fact that UV spectroscopic observations of nearby galaxies have mostly focused on bright, relatively isolated regions of star formation, and not on the integrated light of the galaxies. Combined with the relatively small apertures of space-based spectrometers and the large apparent diameter of the sources, this fact has likely resulted in most of the spectra not sampling the volumes of space affected by the outflows. Some of the FeII lines also seem weak in the seven-galaxy stacked spectrum at \(z \approx 1.9\) shown in Figure 3, but this is due to the relatively low S/N of the individual spectra and to the small number of galaxies entering this stack.

The fact that the full P-Cygni profile, i.e., both absorption and emission components, is not clearly recognized in our spectra (but it is very well detected in the spectra by Rubin et al. 2010a, 2011), especially the emission component of the \(\lambda 2796\) \(\AA\) transition of the MgII doublet, should not come as a surprise in our relatively low resolution spectra.\(^{11}\) As reported by Rubin et al. (2010a, 2010b, 2011) both the fine-structure Fe\(^+\) lines and the P-Cygni MgII feature are observed approximately at the systemic redshift. Thus, the combined effect of the relatively low spectral resolution, the strength and large velocity width of the interstellar absorption, and the fact that a large number of galaxies with different outflow velocities enter the stack (recall that the spectra are put on the rest frame using the redshift of the [OIII] \(\lambda 3727\) nebular line, which traces the systemic redshift of the galaxies, only when the feature is available in the spectral range) is that the emission component of the P-Cygni profile is diluted by the strong interstellar absorption. Because the generally large velocity of the outflowing gas blueshifts the absorption component, some of the MgII \(\lambda 2803\)

\(^{11}\) The resolution of the Keck/LRIS spectra by Rubin et al. (2010a, 2011), where the P-Cygni profile is clearly detected in the spectra of individual galaxies, is \(\approx 2.5\times\) higher than that of our spectra. That of the Keck/DEIMOS spectra by Weiner et al. (2009), who also observe the P-Cygni profile for some of the galaxies, is \(\approx 10\times\) larger.
P-Cygni emission that is located at the systemic redshift survives, and this is what we are most likely observing. The emission line in the GMASS spectrum seems to exhibit an absorption feature, which, as we noted previously, is observed at the same wavelength as the red absorption feature in the red wing of the GOODS spectrum. This apparent trough could give the GMASS Mg ii emission the semblance of a double-peaked line. The emission component of the Mg ii P-Cygni feature is also possibly detected in the GOODS co-added spectrum (see Figures 15 and 16). Finally, we note that a virtually identical spectral morphology of the Mg ii P-Cygni profile is observed in the HST/FOS UV spectra of Tololo 1924-416 by Kinney et al. (1993), which have similar resolution ($R \approx 400$).

Subtracting the Mg ii emission from the spectrum makes the broad “red wing” absorption profile evident in the GMASS co-added spectrum too, showing that it extends to approximately the same velocity separation from Mg ii as the one in the GOODS spectrum, namely, $\Delta V \lesssim 2000$ km s$^{-1}$. This is illustrated in Figure 16, where the dashed line shows the residual continuum after a Gaussian profile has been fitted to the emission line and subtracted. The figure shows a zoom-in of the spectral region around the Mg ii doublet in the co-added spectra of the GMASS background galaxies ($z \approx 1.65$) and of the 33 GMASS and 16 GOODS galaxies. A linear spline fit to the continuum in two spectral regions that bracket the Mg ii doublet ($2650 \, \AA \leq \lambda \leq 2750 \, \AA$ and $2830 \, \AA \leq \lambda \leq 2930 \, \AA$) is also shown for each spectrum to help identify the absorption features. The broad “red wing” absorption feature in the GMASS spectrum of the overdensity galaxies results in part from the removal of the emission line, but also, in large part, from the presence of what look like absorption features immediately to the red of the emission line, marked by a horizontal square bracket in Figure 16. The discrete absorption lines possibly detected in the GOODS co-added spectrum are also marked in the figure.

We emphasize that no “red wing” absorption feature seems to be present in the co-added spectrum of the GMASS background galaxies, namely, spectrum (a) in Figure 15, even if the (weak) emission component of the Mg ii P-Cygni feature is subtracted. About three times more galaxies are included in this spectrum than in that of the overdensity galaxies. Thus, it seems unlikely that in the stack of the overdensity galaxies the feature is the result of some systematics arising during the averaging procedure. For example, one could imagine that deviations of the measured redshift of the galaxies from their systemic value might produce the feature by broadening the galaxies’ interstellar Mg ii $\lambda 2803$ absorption line. Random deviations up to several hundred km s$^{-1}$ will occur for those galaxies where the [O ii] nebular emission line is not available and the redshift is measured from the Mg and Fe interstellar absorption lines, which are typically blueshifted relative to the systemic redshift due to the presence of outflows (Steidel et al. 2010). The co-added spectrum of the background galaxies, whose redshifts are essentially all measured from the interstellar lines, suggests that this is not the case. We have further investigated this possibility by separately co-adding the spectra of the GMASS overdensity galaxies with redshift measured from the [O ii] emission line (19 spectra) and of those with redshift measured from the absorption lines (14 spectra), which are reproduced in Figure 17 as spectra (a) and (b), respectively. Spectrum (a) has a stronger Mg ii P-Cygni emission component, but is otherwise qualitatively very similar to the full stack, i.e., spectrum (b) of Figure 16, with a clear depression of the continuum right to the red of the emission line. Removing the emission line would result in the same “red wing” absorption profile like the one we have illustrated in Figure 16 for the full-stack spectrum. We also note that a “blue wing” absorption is now possibly observed in spectrum (a); this would be the effect of absorption in the outflows, quite similar to that observed in other UV low-ionization metal absorption lines (see Steidel et al. 2010). The “red wing” absorption in spectrum (b) seems to be much weaker. The emission component of the Mg ii P-Cygni feature is also weaker than in spectrum (a), and while removing the feature would result in a broad “red wing” absorption, this would not reach the same extent as in the case of spectrum (a). The “blue wing” due to the outflows, if present, is also very weak. Finally, because the redshift of the individual spectra entering in spectrum (a) is very close to the systemic one, it can be seen that both the Mg ii and Mg i absorption lines are blueshifted, by about 250 km s$^{-1}$, due to the presence of outflows. Obviously, this effect cannot be observed in spectrum (b) because the individual spectra are placed in the rest frame using the redshift of the absorption lines themselves.

It is important to realize that, although subtracting the emission component of the Mg ii P-Cygni feature is a necessary step if one wants to explore gas accretion in quantitative details, we have little guidance on how to objectively carry out the subtraction procedure at this time; our subtraction of a Gaussian fit to the line remains arbitrary. As we have mentioned earlier, the Mg ii P-Cygni feature in star-forming galaxies at high redshift is observed in conjunction with the fine-structure emission lines of Fe ii, but not much else is known about these features and their empirical phenomenology and systematics, e.g., how the line strength of the two species depend on each other and on the properties of the galaxies and/or of the outflows. We are only aware of the photon scattering mechanism proposed by Rubin et al. (2011) and Prochaska et al. (2011) to explain these lines at this time. We have also checked for the possibility that some of the galaxies in our sample might host an AGN, but none is individually detected in the recently released ultra-deep Chandra X-ray image ($T_{\text{exp}} = 4$ Ms; see Gilli et al. 2011) in the Chandra Deep Field South (CDFS). With no guidance from either the theory or the observations, it is not possible to go beyond the qualitative and crude analysis discussed here. Rubin et al. (2010b) follow a similar procedure of fitting and subtracting the emission component of the Mg ii P-Cygni feature (to derive the equivalent width of the Mg ii interstellar absorption) using a five-parameter model that separately accounts for the emission and absorption components. As they discuss, this model does not produce acceptable results for co-added spectra, since it tends to be driven by noise features in the line profiles. Thus, we have decided to avoid the further complication of the model and simply remove the feature after fitting the “local” line profile with a Gaussian since this seems to give comparable results, and our initial goal is to explore the existence and qualitative aspects of cold gas accretion.

Regardless of the details, however, even a very conservative subtraction of the line from the co-added spectra shown in Figures 16 and 17 (such as simply eliminating the local excess flux) results in an obvious “red wing” absorption profile that extends from immediately to the red of the Mg ii interstellar feature to $\Delta V \approx 2000$ km s$^{-1}$ from the systemic wavelength of the Mg ii $\lambda 2803$ line.

The “red wing” absorption profile is observed in both the GMASS and GOODS co-added spectra of galaxies in the $z \approx 1.61$ overdensity but is not observed in the much deeper stacked spectrum of the 92 background galaxies at $z > 1.65$.
Figure 17. Co-added spectra of GMASS galaxies in the $z \sim 1.61$ overdensity. The top spectrum (a) includes galaxies with redshift measured from the [OII] nebular emission line, while the bottom spectrum (b) includes galaxies whose redshift comes from interstellar absorption lines such as FeII and MgII. Spectrum (a) has a stronger emission component of the MgII P-Cygni feature than spectrum (b) of Figure 16, but it is otherwise quite similar to it, including the presence of absorption immediately to the red of the emission line. Removal of the emission line would also result in a “red wing” absorption feature. A possible broad “blue wing” absorption profile is observed immediately to the blue of the MgII $\lambda 2797$ absorption line, too. Broad “red wing” absorption is less clear in spectrum (b); while the removal of the MgII emission line would make it more evident, the absorption profile would not be as extended as in spectrum (a).

in the background, implying that its detection is related to the presence of the overdensity itself. This suggests that the average covering factor of gas around galaxies that belong to the overdensity is substantially larger than that around isolated field galaxies. We plan to return to this issue more quantitatively in an upcoming paper.

6. DISCUSSION AND CONCLUSIONS

Three key results have emerged from this work. The first is the identification of a substantial amount of “cold” gas, i.e., $T \approx 10^4$ K in an overdensity of galaxies at $z \approx 1.61$ that is not directly associated with (i.e., resides in the gaseous halo of) bright galaxies, but rather is either “circum” or “intra” overdensity gas, or both. The gas appears to be chemically younger than the outflows from star-forming galaxies at the same redshift (including the galaxies in the overdensity), which have similar physical conditions (e.g., Tremonti et al. 2007). In other words, the gas is part of the structure and is spatially distributed around and/or within it but it is not part of the galaxies that belong to the structure. This gas has been identified by the MgII absorption that it imprints in the spectra of background LBG at $z \sim 3$, by the absorption feature in the co-added spectra of a large number of galaxies in the background of the overdensity, as well as in the co-added spectrum of galaxies within the overdensity.

We can derive a crude estimate of the average covering factor of the high-column-density gas from the ratio of detected intervening ultra-strong MgII absorption systems, i.e., the four systems in the spectra of G1, G2, and G3, to the number of spectra that have sufficient S/N to detect such systems, namely, the 21 spectra of GOODS LBGs and the 92 spectra of GMASS background galaxies. We find $C_F \sim 4/105 \approx 4\%$. This is consistent with recent current theoretical estimates for isolated galaxies hosted in $M \sim 10^{12} M_\odot$ halos, i.e., $C_F \lesssim 3\%$ at $z \sim 1.5$, and given the fact that our spectra are only sensitive to absorption with large equivalent width, probably even consistent with the expected trend of increasing cold gas covering factor with larger mass, i.e., $C_F \approx 10\%$ around halos with $M \sim 10^{14} M_\odot$ at the same redshift (Kimm et al. 2010). The absorption features observed in the co-added spectra of the background galaxies and of the galaxies in the overdensity suggest the presence of both continuous absorption as well as absorption by discrete clouds, consistent with a projected gas distribution where structures capable of higher column density are embedded in a more diffuse medium. Observationally, the probability that gas clouds intersect the LOS to galaxies should be larger in an overdensity than for background galaxies, since the surface density of the former is enhanced, by about six-fold in our case, versus the latter. Kimm et al. (2010) suggest that the low covering factor around isolated galaxies, coupled with the fact that the interstellar absorption lines are strong and broad in velocity space, are the key factors behind the current lack of detections of cold accretion. Thus, while waiting for the sensitivity of 30 m telescopes, targeting galaxy overdensities seems to be a more efficient way to make some progress.
Essentially no information is available about the spatial morphology of the high-column-density gas, i.e., whether filamentary or not, as predicted by the simulations (e.g., Keres et al. 2005; Dekel et al. 2009a). Curiously, the three LBGs with the intervening Mg ii absorption systems are aligned along a straight line and the spatial separation and velocity difference between the four LBG Mg ii absorbers are consistent with an elongated distribution of the gas: the velocity difference between G1’s absorber and the first one of G2, \(\Delta V \approx 500 \text{ km s}^{-1}\), and their projected spatial separation at \(z \approx 1.61\), \(D \approx 200 \text{ kpc}\), are consistent with them being produced by the same gas mass. A homogeneous cloud would have to be either more massive than \(\approx 2.5 \times 10^{10} M_{\odot}\), the same mass of an \(\approx L^*\) galaxy at the same redshift (Reddy et al. 2008), if roughly spherically symmetric, or be preferentially distributed along the separation between the two absorbers, unless \((C_F) \ll 1\) and we have accidentally hit two spots of high column density. Similarly, the projected separation between the second absorber of G2 and that of G3 is \(\approx 1\) Mpc, and their velocity difference is \(\approx 800 \text{ km s}^{-1}\). If this velocity difference were due to pure Hubble flow, then the physical distance between the two troughs would be \(d = \Delta V / H(z) = 4.6 \text{ Mpc}\), where the Hubble constant \(H_{\text{z}}\) at \(z = 1.61\) is \(H_{\text{z}} = 172 \text{ km s}^{-1} \text{ Mpc}^{-1}\). But these two alignments can very well be just a fortuitous coincidence. If the geometry of the high-column-density gas mass is filamentary, the finite size of the LBG yields a lower limit to the linear mass density along the filament, which is \(\rho_F > 0.8 \times 10^8 \times C_F \times (N_{\text{H}/10^{20} \text{ cm}^{-2}}) \times M_{\odot} (10 \text{ kpc})^{-3}\), where \(C_F\) is the gas average linear covering factor along the filament (which is different form the average volume covering factor \(C_V\) discussed above). If this mass accretes onto some galaxy, as the spectra of galaxies in the \(z \approx 1.61\) overdensity suggest, and is converted into stars, then a lower limit to the star formation rate that the filament can sustain is

\[
\text{SFR} \approx 25 \times C_F \times \left( \frac{N_{\text{H}}}{10^{20} \text{ cm}^{-2}} \right) \times \left( \frac{V_T}{300 \text{ km s}^{-1}} \right) M_{\odot} \text{ yr}^{-1},
\]

where \(V_T\) is the tangential velocity of the gas flow along the filament. This lower limit is in agreement with the star formation rate of galaxies at \(1 < z < 2\) (Daddi et al. 2007; Reddy et al. 2008). The main uncertainties here are the width of the putative filaments and the value of \(C_F\). It is very difficult to make more informative statements without knowing more about the large-scale geometry of the gas. The analysis of a larger number of background probes will bring improvement in this area.

All four intervening LBG Mg ii absorption systems have redshift located in the wings of the redshift distribution of the overdensity, as if they tended to “avoid” the galaxies. It is possible that this is, at least in part, an observational bias due to the presence of night-sky emission lines (albeit weak ones) at the wavelengths of Mg ii at the redshift of the peak. While one could certainly imagine the possibility of astrophysical processes that suppress high-column-density gas clouds inside large concentrations of galaxies, it is hard to reach any conclusion with only four data points. Note, however, that large concentrations of galaxies, such as ours, marked by spikes in the redshift distribution, do not have properties commonly associated with galaxy clusters, although they might evolve into one (e.g., Kurk et al. 2009). Their spatial extent is much larger, by at least by one order of magnitude, than clusters and thus their galaxy density is lower by about three orders of magnitude; no diffuse X-ray emission is observed from them, as we directly verified in our case using the ultra-deep Chandra X-ray images in the CDFS. In any case, however, the existence of high-column-density gas clouds around such structures seems real, with velocity separations that can reach up to \(\approx 2000 \text{ km s}^{-1}\), as evidenced not only by the LBG absorption systems, but also by the absorption features observed in the GMASS co-added spectra of both background and overdensity galaxies. The observation of the “red wing” absorption profile seems to suggest that this might very well be gas associated with cold accretion onto the structure.

Information on the kinematics of the absorbing gas is minimal from the current low resolution and, in the case of the four LBG absorption systems, low S/N spectra. Since the absorption lines are very likely saturated, their velocity width mostly reflects the velocity spread of the gas along the LOS, which is less than a few hundred km s\(^{-1}\). While this is certainly consistent with the general idea that the gas in cold streams is expected to be kinematically “cold” (the line broadening contributed by the temperature of the gas, \(T \approx 10^4\), is small, of the order of \(\approx 10^4 \text{ km s}^{-1}\)), it offers little insight into the dynamics of the gas, especially since we do not know much about the spatial geometry of the absorbing troughs.

The second key result is that the cold, \(T \approx 10^4\) K gas appears to be chemically more pristine than the ISM and the gas outflows from galaxies at similar redshift, including those galaxies that belong to the overdensity. This evidence comes from the lack of absorption by Fe (i.e., the absorption lines Fe ii 2587 and Fe ii 2600) in the co-added spectrum of the absorption systems detected in the spectra of G1, G2, and G3, and in the co-added spectrum of the 92 GMASS galaxies in the background of the overdensity. Interstellar absorption lines by Fe ii and Mg ii typically have similar strengths at both low and high redshifts, as documented by numerous works (e.g., Leitherer et al. 2011; Weiner et al. 2009; Rubin et al. 2010a, 2010b) and as illustrated here by the stacked spectra of both local and high-redshift galaxies. All our co-added spectra of galaxies have both Mg and Fe absorption lines with approximately equal strength, but the co-added spectra of the four LBG absorption systems and that of the 92 GMASS \(z > 1.65\) background galaxies (not registered to the rest frame) only have Mg ii absorption. A crude lower limit to the \(\alpha/Fe\) ratio derived from the ratio between the observed Mg ii equivalent width and the upper limit to the Fe ii one shows that the gas has a different enrichment pattern than that observed in galaxies. A calculation made with CLOUDY shows that the column density ratio of Mg ii to Fe ii is expected to be around unity, assuming a medium with one-tenth solar metallicity, solar elemental ratio, DLA-like H i column density, and the Haardt & Madau (1997) spectrum of metagalactic ionizing radiation. Thus, our finding suggests that the cold gas we have identified has a deficiency of Fe-peak relative to \(\alpha\)-elements, implying that it is very likely chemically younger and underwent a different enrichment history than the ISM of galaxies at the same redshift, including the outflows from star-forming ones. A possibility is that this is relatively pristine cosmic gas, pre-enriched by earlier generations of stars than those forming in the galaxies of the \(z \approx 1.6\) overdensity. The overabundance of \(\alpha\)-elements over Fe-peak would result from core-collapse (Type II) SNe preferentially enriching the IGM relative to Type Ia. Whether this overabundance of \(\alpha\)-elements over Fe is due to the time delay between the occurrence of Type Ia relative to Type II events or to a top-heavy IMF, or both, cannot be addressed here.

Finally, the third key result of this paper is the possible direct detection of accretion of cold gas on the galaxies of the overdensity or on the overdensity itself. This evidence, which
the outflows of star-forming galaxies); (2) a characterization of the geometry and spatial extent of the high-column-density gas, both at large scales and in proximity of galaxies; and (3) robust kinematical evidence that the gas is moving in bulk motions and accreting onto the galaxies.

Luckily, the prospect for progress seems good, even with available technology and instrumentation. Larger surveys for intervening galaxy Mg \( \text{II} \) absorption systems in the background of large cosmic structures with denser spatial sampling than presented here can be done within current capabilities by acquiring larger and, to some extent, deeper samples. These will not only provide a much more robust characterization of the accretion kinematics, but will also better constrain the geometry and spatial extent of the gas. Dedicated ultra-deep observations of bright galaxies can even yield direct estimates of the H\( \text{I} \) column density from the DLA feature that gas (at slightly higher redshift than that discussed here) with \( N_{\text{HI}} > 2 \times 10^{20} \text{ cm}^{-2} \) should imprint onto the UV spectra of the galaxies. Another distinct advantage of such an approach is that it offers an independent methodology to investigate gas inflows with radically different selection bias than the more traditional one of studying the CGM back-illuminated by the background UV light provided by the galaxy’s own stars (Steidel et al. 2010). This methodology is effective in characterizing the outflows from star-forming galaxies. But we do not understand, at present, if and how the selection bias inherent in such an approach affects the observability of gas inflows, especially in isolated, field galaxies. Our approach of targeting the environment of large structures and using redder portions of the UV SED of star-forming galaxies, where the strong Mg and Fe features are located, appears promising and worth exploring further.
