We present a test of the local Lorentz invariance of post-Newtonian gravity by monitoring Earth’s gravity with a Mach-Zehnder atom interferometer that features a resolution of about $8 \times 10^{-7} \text{g}/\sqrt{\text{Hz}}$, the highest reported thus far. Expressed within the standard model extension (SME) or Nordtvedt’s anisotropic universe model, the analysis limits four coefficients describing anisotropic gravity at the ppb level and three others, for the first time, at the 10ppm level. Using the SME we explicitly demonstrate how the experiment actually compares the isotropy of gravity and electromagnetism.

PACS numbers: 03.75.Dg, 11.30.Cp, 11.30.Qc, 04.25.Nx

The description of gravitation by a dynamic geometry of space-time, Einstein’s general relativity (GR), is based on the Einstein equivalence principle. This encompasses the universality of free fall (UFF), local position invariance (LPI), and local Lorentz invariance (LLI), which also underlies the non-gravitational standard model of particle physics. Attempts to unify GR and the standard model have failed so far. This suggests that one of their foundations might be violated at some level of precision\footnote{Electronic address: holgerm@stanford.edu}. So far, tests of the UFF and LPI have not identified violations\footnote{Electronic address: holgerm@stanford.edu}. LLI has been tested experimentally for many sectors of the standard model, such as for photons (‘Maxwell sector’), electrons, protons, and neutrons\footnote{Electronic address: holgerm@stanford.edu}. No Lorentz violation has been identified, although the coverage of parameter space is still incomplete. Far less attention, however, has been paid to the LLI of the gravitational (‘Einstein’) sector, in spite of the pioneering work of Nordtvedt and Will in the 1970ies. Motivated by that fact that anisotropies arise in various theories of gravity other than GR\footnote{Electronic address: holgerm@stanford.edu}, they have ruled out a Lorentz-violating anisotropy in gravity by searching for an anomalous time-dependence of the acceleration of free fall $g$ on Earth\footnote{Electronic address: holgerm@stanford.edu}.

The success of GR and the standard model implies that any Lorentz violations are tiny. This and the relative weakness of gravity means that only exceptionally sensitive experiments can hope to detect Lorentz violation in gravity. A relatively recent addition to these is precision atom interferometry\footnote{Electronic address: holgerm@stanford.edu}.\footnote{Electronic address: holgerm@stanford.edu}.\footnote{Electronic address: holgerm@stanford.edu}. This has been serving, for example, in measurements of the fine structure constant\footnote{Electronic address: holgerm@stanford.edu}, its gradient\footnote{Electronic address: holgerm@stanford.edu}, the Sagnac effect\footnote{Electronic address: holgerm@stanford.edu}, and Newton’s constant $G$\footnote{Electronic address: holgerm@stanford.edu} with sensitivities that compare favorably with other state-of-the-art instruments. One reason for its outstanding precision is that the motion of neutral atoms can realize a freely falling frame to a high accuracy and that this motion can be interrogated by laser radiation in a tremendously precise way. As a result, tests of post-Newtonian gravity with atom interferometry have been proposed that could rival or exceed the precision of classical ones\footnote{Electronic address: holgerm@stanford.edu}.

Here, we report on a first step in this direction: We describe the highest resolution atomic gravimeter reported thus far\footnote{Electronic address: holgerm@stanford.edu}.\footnote{Electronic address: holgerm@stanford.edu}.\footnote{Electronic address: holgerm@stanford.edu}.\footnote{Electronic address: holgerm@stanford.edu}. We then analyze the influence of Lorentz violation in gravity. By explicitly including possible Lorentz violation in electrodynamics, we explicitly show how this (like any) isotropy test is actually a comparison of two sectors. Finally, we report a test of the LLI of post-Newtonian gravity by testing its isotropy.

Our experimental setup (Fig. 2) assembles about $10^9$ Cs atoms within 650 ms from a background vapor pressure of $\sim 10^{-9} \text{mbar}$ in a 3-dimensional magneto-optical trap (3D-MOT). A moving optical molasses launch accelerates them vertically upwards to a $\sim 1-\text{ms}$ ballistic trajectory with a temperature of 1.2-2 $\mu \text{K}$. Raman sideband cooling in a co-moving optical lattice results in $\sim 3 \times 10^8$ atoms in the $F=3, m_F=3$ state at a (3D) temperature of 150 $\mu \text{K}$ that form a cloud of roughly $3 \text{mm}^2$ area\footnote{Electronic address: holgerm@stanford.edu}.\footnote{Electronic address: holgerm@stanford.edu}. A sudden change in the magnetic field followed by a 120-$\mu \text{s}$ microwave pulse transfers $\sim 20\%$ of them into the $F=4, m_F=0$ state. Atoms left over in the $F=3$ state are then cleared away using a resonant laser pulse. A solenoid generates a small magnetic bias field to set the quantization axis.

Afterwards, a $\pi/2$ pulse of counterpropagating laser beams, overlapped with the trajectory of the atoms, transfers the atoms into a superposition of the $F=3$ and $F=4$ hyperfine ground states by a two-photon Raman transition (Fig. 1 left). These states move vertically relative to each other because of the momentum of two photons transferred by the laser radiation. After a time $T \approx 0.4 \text{s}$, a $\pi$ pulse interchanges the $F=3$ and 4 states, which afterwards move towards each other. After another $T$, a final $\pi/2$ pulse recombines the paths to form...
The off-resonant Raman pulses are generated by two extended cavity diode lasers based on 100-mW laser diodes SDL-5411. The first is frequency stabilized ('locked') by Doppler-free frequency modulation (FM) spectroscopy to a Cs vapor cell. It arrives at the interferometer via a common single-mode, polarization splitting of X20, X64. Right: Typical fringe obtained in our experiment

Fig. 1 (right) shows a typical fringe with a pulse separation time of \( T = 400 \text{ ms} \), taken with 40 launches that take 75 s total. A sinewave-fit has a phase uncertainty of 0.031 \( \text{rad} \), and determines \( g \) to an uncertainty of \( \sim 1.3 \times 10^{-9} \text{ g} \). This corresponds to \( 11 \times 10^{-9} \text{ g}/\sqrt{\text{Hz}} \). An improved short-term resolution of \( 8 \times 10^{-9} \text{ g}/\sqrt{\text{Hz}} \) can be reached by taking data at the 50% points of the fringes only. However, as this method is more sensitive to systematic effects such as drift of the PMT sensitivity \( 10 \), this approach was not followed. Our resolution is more than 3 times better than the best previously reported \( 10 \). It also surpasses the best classical absolute gravimeter, the FG-5 falling corner cube gravimeter, by a factor of about 20.

The notion that gravity might depend on the direction of the separation \( \vec{r} \) could be described in very simple terms. For this work, however, we want to use a model that is as general as possible on the one hand and compatible with accepted principles that underlie the standard model and gravitational theory on the other hand. Two such models suggest themselves, Nordtvedt’s anisotropic universe model \( 3 \) and the standard model extension (SME) \( 2, 18 \). The SME starts from a Lagrangian formulation of the standard model and gravity, adding general Lorentz violating terms that can be formed from the fields and tensors. For the gravitational fields present on Earth, a post-Newtonian approximation is justified. For two masses \( M \) and \( m \), separated by \( \vec{r} \), where \( M \) is assumed to be at rest, the Lagrangian for the gravitational interaction in the SME is \( 18 \)

\[
\mathcal{L} = \frac{1}{2} m v^2 + G \frac{M m}{2r} (2 + 3 s^{00}) + s^{jk} \tilde{\rho}^{jk} - 3 s^{0j} \tilde{v}^j - s^{0j} \tilde{v}^j  \tilde{v}^k \tilde{v}^k .
\]

The indices \( j, k \) denote the spatial coordinates, \( \vec{v} \) the relative velocity, and \( \tilde{\vec{r}} = \vec{r}/r \). \( \tilde{s}^{\mu \nu} = s^{\mu \nu} \) specifies Lorentz violation in gravity. The two-body Lagrangian of the anisotropic universe model is similar, but \( s^{00} = 0 \) and the coefficients of the \( v^j \) and the \( \tilde{\rho}^{jk} v^k \tilde{v}^k \) terms are independent of each other. The equation of motion (simplified by using \( v \ll 1 \) and neglecting constant as well as
horizontal accelerations) reads
\[ \ddot{r}^i + \dot{r}^i \frac{GM}{2r^2} (2 + z^k \dot{r}^j \dot{r}^k) = 0 \] (3)
where the coefficient of \( \ddot{r}^i \) gives the modified acceleration of free fall.

One outstanding feature of atom interferometry is the relative simplicity of the underlying theoretical assumptions, which can be traced to its relying on non-relativistic single-particle effects. This allows us to analyze the experiment without assuming the LLI of the Maxwell sector. We therefore determine \( k_{\text{eff}} \) in Eq. (11) from the dispersion relation for photons having a frequency of \( \omega_0 \) of the SME (neglecting Lorentz-violating birefringence, which astrophysics experiments bound to \( < 10^{-37} \)) [19], and a constant) [20]

\[ k = \omega_0 \left[ 1 - \frac{1}{2} (k_F)^{\alpha \omega \omega} \kappa_1 \kappa_2 - (k_F)^{\alpha \omega \omega} \right], \] (4)

where \( k_F \) specifies Lorentz violation in the Maxwell sector. As \( \kappa_{\text{eff}} = \kappa_1 - \kappa_2 \), where \( \kappa \simeq \tilde{k}_1 \simeq -\tilde{k}_2 \), the last term cancels out. In our experiment the beams are vertical, \( k = \tilde{k}/k = \hat{r} \). Thus, Eq. (11) reads

\[ \phi = 2k_0 g_0 \left[ 1 + \frac{1}{2} (k_F)^{\alpha \omega \omega} \right] T^2 - \phi_0. \] (5)

where \( g_0 = GM/r^2 \) and \( k_0 = \omega_0(c0) [21] \). Thus, the measured anisotropy is given by \( \sigma^{\alpha \omega \omega} \sim \tilde{k} - (k_F)^{\alpha \omega \omega} \). Various definitions of coordinates and fields can still be made, that could be chosen to yield \( (k_F)^{\alpha \omega \omega} = 0 \).

By coordinate transformations from an inertial sun-centered celestial equatorial frame (denoted with capital indices \( J, K \)) into the laboratory frame on Earth [18] we obtain the time-dependence

\[ \frac{\delta g}{g_0} = \sum_m C_m \cos(\omega_m t + \phi_m) + D_m \sin(\omega_m t + \phi_m) \] (6)

of the \( g \)-modulations. The coefficients \( C_m, D_m \) for the six frequencies \( 2\omega, \omega, \omega \pm \Omega, 2\omega \pm \Omega \) are functions of the components of \( \sigma^{\mu \nu} \), of Earth’s orbital velocity \( v/c \simeq 10^{-4} \), and the frequencies of Earth’s orbit’s \( \Omega = 2\pi/(1 \text{y}) \) and rotation \( \omega \sim 2\pi/(23.93 \text{h}) \).

For bouncing post-Newtonian gravity, we use \( \sim 60 \text{h} \) of data taken with this setup, as well as a \( \sim 60 \text{h} \) and a \( \sim 10 \text{d} \) run reported previously [11], see Fig. 3. Periodic changes having an amplitude of around 100 \( \mu \text{gal} \simeq 10^{-7} \mu \text{gal} \) are due to tides. Subtraction of a Newtonian model based on the relative positions of the Sun, the Moon, and the planets [22] yields the graph shown at the bottom of Fig. 3. More sophisticated tidal models are available [24] that take into account ocean loading and local effects. However, such models typically rely, in part, on fitting \( g \)-observations and are thus not suitable for our purpose of comparing to a Newtonian model.

The combined data spans about 1500d, but fragmented into three relatively short segments. A Fourier analysis yields the components given in Tab. 1. The fragmentation of the data leads to significant overlap, as given by a covariance matrix \( \text{cov} \). To remove the overlap, we form linear combinations using \( \text{cov}^{-1} \), see Tab. 1. The error in this estimate, given as the geometric sum of the errors entering the linear combinations, increases in this process.

Comparing the modulations of \( g \) given by Eq. (6) to the measurement, we obtain the estimates listed in the fourth column of Tab. 1. \( \sigma^{TY} \) is measured as a linear combination with \( \sigma^{TY} \), into which we insert \( \sigma^{TY} \) as previously determined. Some components are multiply determined and could be combined to a weighted average, but in all cases one limit strongly outweighs the others. Our final results are (parts in \( 10^9 \))

\[ \sigma^{XX} - \sigma^{YY} = -5.6(21), \quad \sigma^{XY} = -0.09(79), \]
\[ \sigma^{XZ} = -13(37), \quad \sigma^{YZ} = -61(38) \] (7)

and (parts in \( 10^{10} \))

\[ \sigma^{TY} = -2.0(4.4), \quad \sigma^{TX} = 5.4(4.5), \]
\[ \sigma^{TZ} = 1.1(26). \] (8)
In this letter, we have reported three types of results: First, a gravimeter based on cold atoms, which uses a pulse separation of $T = 400$ ms and a bright source of Cs atoms using Raman sideband cooling in an optical lattice to reach a resolution of $(8 - 11) \times 10^{-9} \, g/\sqrt{\text{Hz}}$. Second, we analyze the expected modulation of the local gravitational acceleration apparent in this experiment as a result of Lorentz violation in both post-Newtonian gravity and electromagnetism. Third, our test of the isotropy of post-Newtonian gravity bounds four combinations of $\sigma^{J^R}$ to the $10^{-9}$ level and the three $\sigma^{00}$ to the $10^{-5}$ level. Whereas most tests of gravity are astrophysical in nature, ours is a laboratory experiment, which offers reproducibility and superior control over relevant parameters.

A previous order-of-magnitude limit $|s^{J^R}| \leq 4 \times 10^{-9}$ exists, translated \cite{18} from the anisotropic universe bounds due to Nordtvedt \cite{3}. No such previous limits on the $\hat{s}^{TJ}$ are known to us. A forthcoming publication derives bounds on $s$ from 34 years of lunar laser ranging (LLR) data that complement our laboratory bounds \cite{23}. We note, however, that ours is the first experiment where the simultaneous influence of the non-gravitational and gravitational effects are understood quantitatively and which accordingly states combined bounds. For other experiments, these influences are not understood at present. Moreover, the results differ vastly in the orbit (if one can think of the atoms’ trajectory as an orbit) and quantum-mechanical nature of the test masses. This is interesting, as quantum gravity might conceivably involve phenomena that couple to coherent quantum states but not classical objects.

Future bounds may be found by use of torsion balances, $g$-data that is routinely taken in geophysical research, or the gravity probe-B satellite. It is also interesting to study horizontal interferometer geometries, as they might offer suppression of tidal influences, which is the main factor limiting our resolution. In addition, lifting our assumption that UFF is valid, our data could be analyzed for bounds on $a$- and $c$- type SME matter coefficients \cite{26}. We remark that gravity yields space-time varying contributions to $k_F$ related to Nambu-Goldstone modes \cite{27}; our analysis uses a flat space-time picture where those are averaged over \cite{18}. This is likely to yield higher-order corrections that are currently being investigated \cite{26}. The gravimeter itself is still not limited by any fundamental limits such as quantum projection noise. With $\sim 10^8$ atoms per launch, a quantum projection limited gravimeter could reach the $10^{-12} g$ level per launch and $10^{-14} g$ per day, if other noise sources (notably phase noise and vibrations) can be controlled. This promises improved tests of gravity based on atom interferometry, deepening our understanding of the fundamental principles of Nature.

We thank A. Peters, Q.G. Bailey, J. Overduin, V.A. Kostelecky, and A. Mulch for valuable contributions. This material is based upon work supported by the National Science Foundation under Grant No. 0400866, the Air Force Office of Scientific Research, and the Multi-University Research Initiative.
