ABSTRACT

We use observations of cosmic microwave background anisotropies, supernova luminosities and the baryon acoustic oscillation signal in the galaxy distribution to constrain the cosmological parameters in a simple interacting dark energy model with a time-varying equation of state. Using a Monte Carlo Markov Chain technique we determine the posterior likelihoods. Constraints from the individual data sets are weak, but the combination of the three data sets confines the interaction constant $\Gamma$ to be less than 23% of the expansion rate of the Universe $H_0$; at 95% CL $-0.23 < \Gamma/H_0 < +0.15$. The CMB acoustic peaks can be well fitted even if the interaction rate is much larger, but this requires a larger or smaller (depending on the sign of interaction) matter density today than in the non-interacting model. Due to this degeneracy between the matter density and the interaction rate, the only observable effect on the CMB is a larger or smaller integrated Sachs–Wolfe effect. While SN or BAO data alone do not set any direct constraints on the interaction, they exclude the models with very large matter density, and hence indirectly constrain the interaction rate when jointly analysed with the CMB data. To enable the analysis described in this paper, we present in a companion paper [arXiv:0907.4981] a new systematic analysis of the early radiation era solution to find the adiabatic initial conditions for the Boltzmann integration.

1 INTERACTING DARK ENERGY

Dark energy and dark matter are the dominant sources in the ‘standard’ model for the evolution of the universe. Both are currently only detected via their gravitational effects, with an inevitable degeneracy between them (one requires a model to separate dark energy from dark matter). There could thus be an interaction between them that is consistent with current observational constraints. A dark sector interaction could also alleviate the ‘coincidence’ problem (why are the energy densities of the two components of the same order of magnitude today?). Furthermore, interacting dark energy exerts a non-gravitational ‘drag’ on dark matter, and thus can introduce new features to structure formation, including possibly a new large-scale bias [Amendola & Tonchini-Valentini 2002] and a violation by dark matter of the weak equivalence principle on cosmological scales [Bertolami et al. 2007; Koyama et al. 2009].

The energy balance equations in the background are

\[ \dot{\rho}_c = -3H\rho_c + aQ_c , \tag{1} \]
\[ \dot{\rho}_{dc} = -3H(1 + w_{dc})\rho_{dc} + aQ_{dc} , \tag{2} \]

where $a$ is the scale factor of the Universe, $H = a'/a$ is the conformal Hubble parameter, $w_{dc} = p_{dc}/\rho_{dc}$ is the dark energy equation of state parameter, a prime indicates derivative with respect to conformal time $\tau$, and $Q_c$ is the rate of transfer to the dark matter density due to the interaction.

Various forms for $Q_c$ have been put forward (see, e.g. Wetterich [1995]; Amendola [1999]; Billyard & Coley [2000]; Zimdahl & Pavon [2001]; Farrar & Peebles [2004]; Chimento et al. [2003]; Olivares et al. [2005]; Koivisto [2005]; Sadjadi & Alimohammadi [2006]; Guo et al. [2007]; Boehmer et al. [2008]; He & Wang [2008]; Quentin et al. [2008]; Pereira & Jesus [2009]; Quercellini et al. [2008]; Valiviita et al. [2008]; He et al. [2009]; Bean et al. [2008]; Chongchitnan [2009]; Corasaniti [2008]; Caldera-Cabral et al. [2009]; Gavela et al. [2009]; Jackson et al. [2009]). All of these models are phenomenological. Some of them are constructed specifically for mathematical simplicity – for example, models in which $Q_c \propto \mathcal{H} \rho$. Rather than design the interaction to achieve a specific outcome, we prefer to start with a simple physical model, and then develop its predictions.
We consider models which are similar to simple models of reheating (Turner 1983), of dark matter decay into radiation (Cen 2001), and of curvaton decay (Malik et al. 2003) – i.e., where the interaction has the form of a decay of one species into another, with constant decay rate. Such a model was introduced in Boehmer et al. (2008); Valiviita et al. 2003) – i.e., where the interaction has the form of a decay of one species into another, with constant decay rate. Such a model was introduced in Boehmer et al. (2008); Valiviita et al. 2003):

$$Q_c = -\Gamma \rho_c,$$

where $\Gamma$ is the constant positive decay rate of dark matter to dark energy. Here, as well as in Valiviita et al. 2008, we include also the possibility $\Gamma < 0$, i.e., allow also for energy transfer is from dark energy to dark matter.

In Valiviita, Majerotto & Maartens 2008 we considered the case of fluid dark energy with a constant equation of state parameter $-1 < w_{de} \leq -4/5$, and found that a serious large-scale non-adiabatic instability affects this model in the early radiation dominated epoch. This instability is stronger the closer $w_{de}$ is to $-1$. Phantom models, $w_{de} < -1$, do not suffer from this instability, but we consider them to be unphysical.

The instability is determined by the early-time value of $w_{de}$: for constant $w_{de}$, there is no flexibility, but a variable $w_{de}$ (as in quintessence models, see e.g. Lee et al. 2006) should allow us to avoid the instability. We show that the models are viable if $w_{de} > -4/5$ at early times, while at late times, $w_{de} \sim -1$. We represent $w_{de}$ via the parametrization

$$w_{de} = w_0 + w_a (1 - a)$$

(Chevallier & Polarski 2001; Linder 2003), which we rewrite as

$$w_{de} = w_0 a + w_a (1 - a),$$

where $w_a = w_0 + w_a$ is the early-time value of $w_{de}$, while $w_0$ is the late-time value. This parametrization was originally developed to phenomenologically account for the possible time evolution of $w_{de}$ up to redshifts of a few. At higher redshifts it describes the simplest possible model where $w_{de}$ is a constant, namely $w_a$. In particular, this parametrization works well for some classes of quintessence models (Caldwell & Linder 2005) and it has the advantage of having a finite value at high redshifts. Using a parametrisation for $w_{de}$ has the drawback that it cannot reproduce all possible models for a large redshift range. Furthermore, it is not possible to compute the speed of sound but it is necessary to assume a value for it. It might be interesting to look at different parametrisations of $w_{de}$ or a definite scalar field model. This is left for future work. In this paper we demonstrate with the simple parametrisation, Eq. [3], that a (suitably) time-varying $w_{de}$ cures the interacting model, Eq. [3], from the early-time large-scale instability, and thus provides a viable cosmology.

We perform a full Monte Carlo Markov Chain (MCMC) likelihood scan for the spatially flat interacting and non-interacting models, using a modification of the CAMB (Lewis et al. 2000) Boltzmann code, to determine the best-fitting values of $\Gamma/H_0$ and the other cosmological parameters, against Wilkinson Microwave Anisotropy Probe (WMAP) 5-years data (Komatsu et al. 2009), Supernovae Ia (SN) Union sample data (Kowalski et al. 2008), and data points for the ratio of the sound horizon to a distance measure at two different redshifts from baryon acoustic oscillation (BAO) observations (Percival et al. 2007). The best-fitting models with various combinations of data are shown in Table A2 on page 14 in Appendix A while Fig. 1 above summarizes our main findings for the posterior likelihoods. Our most stringent results for the interacting model result from the combined analysis of WMAP&SN&BAO, giving the following minimal 95% intervals: $\omega_b \in (0.0212, 0.0241)$, $\omega_c \in (0.859, 0.125)$, $H_0 \in (63, 70)$, $\tau \in (0.057, 0.133)$, $\Gamma/H_0 \in (-0.23, +0.15)$, $w_{de} \in (-0.80, -0.19)$, $w_0 \in (-1.00, -0.63)$, $n_S \in (0.937, 1.002)$, ln$(10^{10} A_s) \in (2.95, 3.14)$, $\Omega_{de0} \in (0.648, 0.767)$, $\Omega_{e0} \in (13.6, 14.3)$ Gyr. Description and prior ranges of these parameters are given in Appendix A. There, in Table A1, we also list the definitions of some of the symbols used in this paper.

The key features of the constraints on the interacting model from data may be summarized as follows.

- Any of the data sets alone (CMB, or SN, or BAO) would allow for large interaction: $|\Gamma|$ could be even larger than...
Observational constraints on an interacting dark energy model

Table 1. The evolution of perturbations on super-Hubble scales with various values of the dark energy equation of state parameter in the radiation and matter dominated eras. “Adiabatic” means that it is possible to specify adiabatic initial conditions so that the total gauge invariant curvature perturbation $\zeta$ stays constant on super-Hubble scales, and the evolution of all non-dark energy perturbations is the same as in the non-interacting case while the $\delta_e$ perturbations behave differently. “Adiabatic (standard)” means that the behaviour of all perturbations at early times on super-Hubble scales is the same as in the non-interacting model.

| $w_{de}$ in the RD or MD era | Radiation dominated era (RD) | Matter dominated era (MD) | Viable? |
|-----------------------------|-------------------------------|--------------------------|--------|
| $w_{de} < -1$               | adiabatic                     | adiabatic                | viable, but phantom |
| $-1 < w_{de} < -4/5$        | “blow-up” isocurvature growth | “blow-up” isocurvature growth | non-viable |
| $-4/5 < w_{de} < -2/3$      | adiabatic                     | isocurvature growth      | viable, if $|\Gamma|$ small enough |
| $-2/3 < w_{de} < -1/2$      | adiabatic (standard)          | adiabatic                | viable |
| $-1/2 < w_{de} < +1/3$      | adiabatic (standard)          | adiabatic                | viable |

---

today’s Hubble rate $H_0$. In the CMB the only hint from a large interaction rate is a modified integrated Sachs–Wolfe (ISW) effect. However, due to the cosmic variance the $\chi^2$ is only mildly affected:

- A large negative $\Gamma$ fits the CMB TT and TE spectra equally well as the $\Gamma = 0$ model, but a good fit requires a larger physical cold dark matter density today, $\omega_c$, (and hence a smaller $\Omega_{\text{m,0}}$) and a larger $H_0$. Negative $\Gamma$ suppresses the late ISW effect and hence the CMB fit is slightly better than in the $\Gamma = 0$ case. Combining the CMB data with either SN or BAO or SN&BAO data, this improvement is cancelled by a worse fit to SN and BAO due to too little acceleration at low redshifts.

- Models with large positive $\Gamma$ fit the high-$l$ CMB TT and all TE data equally well as the $\Gamma = 0$ model, but a good fit requires a smaller $\omega_c$ (and hence a larger $\Omega_{\text{m,0}}$) and a larger $H_0$. The SN and BAO data can be fitted better than in the $\Gamma = 0$ case due to increased acceleration at small redshifts. However, this improvement is cancelled by a worse fit to the low-$l$ CMB TT spectrum due to a large late ISW effect.

There are two critical features of the analysis of interacting models, which are not always properly accounted for in the literature:

- The background energy transfer rate $Q_e$ does not in itself determine the interaction in the perturbed universe: one must also specify the momentum transfer rate. We do this via a physical assumption, i.e., that the momentum transfer vanishes in the dark matter rest-frame, so that the energy-momentum transfer rate is given covariantly (Valiviita et al. 2008) by

\[ Q_e = Q_e u_e^i = -Q_{de}^i, \quad Q_e = -\Gamma \rho_c (1 + \delta_c), \quad (5) \]

where $u_e^i$ is the dark matter 4-velocity, and $\delta_c = \delta \rho_c / \rho_c$ is the cold dark matter (CDM) density contrast.

- Adiabatic initial conditions in the presence of a dark sector interaction require a careful analysis of the early-radiation solution. We derive these initial conditions in the companion paper (Majerotto, Valiviita & Maartens 2009) by generalizing the methods of Doran et al. (2003) to the interacting case, extending our previous results (Valiviita et al. 2008). The key results for the initial conditions and early-time perturbation evolution are reproduced in Table 1.

We give here the first analysis of the CMB spectra and the first MCMC likelihood analysis for the interacting model (3), using the perturbation equations and initial conditions given in the companion paper (Majerotto, Valiviita & Maartens 2009). Cosmological perturbations of other interacting models have been investigated in Amen-dola et al. (2003); Koivisto (2005); Olives et al. (2006); Munnini & Bonometto (2007); Bean et al. (2008); Vergani et al. (2009); Pettorino & Baccigalupi (2008); Schaefer (2008); Schaefer et al. (2008); La Vacca & Colombino (2008); He et al. (2009); Bean et al. (2008); Corasaniti (2008); Chongchitnan (2009); Jackson et al. (2009); Gavela et al. (2009); La Vacca et al. (2009); He et al. (2009); Caldera-Cabral et al. (2009); He et al. (2009); Koyama et al. (2009); Kristiansen et al. (2009).

2 PHENOMENOLOGY

We have performed 7 MCMC runs for the spatially flat ($\Omega = 1$) interacting model with various data sets (WMAP, WMAP&ACBAR, SN, BAO, WMAP&SN, WMAP&BAO, and WMAP&SN&BAO). Here WMAP refers to the 5-year temperature and polarization anisotropy data (Komatsu et al. 2009), ACBAR to the Arcminute Cosmology Bolometer Array Receiver data, SN to the Union Supernovae Ia sample (Kowalski et al. 2008) as implemented in CosmoMC (Lewis & Bridle 2002; Lewis & Bridle 2008) with systematic errors flag turned on, and BAO to the two data points $r_s(z_{\text{dec}})/D_V (z = 0.2)$ and $r_s(z_{\text{dec}})/D_V (z = 0.35)$ from Percival et al. (2007). For reference we have done also 6 MCMC runs (excluding WMAP&ACBAR from the above list) for the spatially flat non-interacting model. Each of these 13 runs has 3–4 chains with mean input multiplicity in the range 3–10, and the number of accepted models in each chain is $\sim 25000$. The measure of mixing, the worst eigenvalue $R - 1$ (which is better the closer it is to zero), is for all cases less than 0.03. More technical details are given in Appendix A.

Table A2 on page 14 in Appendix B collects the best-fitting models of each run (excluding WMAP&ACBAR). In addition, we show for each data-set two relatively good-fit models with a strong negative/positive interaction ($|\Gamma|/H_0 > 0.1$) which are not ‘far’ from the best-fitting non-interacting model – in a sense that $\Delta \chi^2 = \chi^2$ (strong interaction model) – $\chi^2$ (best-fitting model) $< 4$. In the last four rows of the table (Models 25–28) we show interacting models which have most of their parameters equal to the WMAP best-fitting non-interacting model (Model 1).
Fig. 2. Models with most of their parameters equal to the parameters of the best-fitting to WMAP non-interacting model.

the WMAP best-fitting non-interacting model (Model 1; thin green/grey line) fits well all the data. The only exceptions are that it fails to fit the low quadrupole \( l = 2 \) in the WMAP TT spectrum, and undershoots both the \( z = 0.20 \) and \( z = 0.35 \) BAO data points, whose error bars are smaller than the asterisk symbol in the plot. Therefore it would be surprising if the interacting model could fit the data overall much better. Now we take Model 1 and turn the interaction on to \( \Gamma/H_0 = 0.3 \) (Models 25 and 26). The negative (positive) interaction leads to an extremely bad fit to the CMB TT data, as the the model now vastly overshoots (undershoots) the first and second acoustic peaks. This is also reflected in the TE spectrum where the peak at \( l \sim 300 \) is overshot (undershot). The SN data cannot distinguish the interacting model from the non-interacting model, though there is a tiny difference: a negative (positive) interaction leads to a faster (slower) increase of the distance modulus as a function of redshift than seen in the non-interacting model, and hence to a slightly better (worse) fit to the SN data. Finally, a negative interaction helps fitting the BAO data as it systematically shifts \( r_s(z_{dec})/D_V(z) \) upward. A positive interaction makes the fit to BAO data worse. All these remarks are reflected in the \( \chi^2 \) values presented in Table A2.

It is quite straightforward to understand why a negative interaction helps in fitting the SN and BAO data. The negative interaction means that the energy transfer is from dark energy to dark matter. As we have kept today’s values of \( \omega_c \) (and \( \Omega_{de0} \)) and \( H_0 \) fixed, this means that in the negatively interacting model there has been more dark energy in the past than in the non-interacting model. This causes more acceleration of the expansion of the universe, and hence larger distance moduli at high redshifts. In the BAO the distance measure is in the denominator, and at first sight one would expect smaller \( r_s(z_{dec})/D_V(z) \) than in the non-interacting case. However, as \( D_V \) is proportional to \( D_A(z) \) the effect of an increased angular diameter distance, \( D_A(z) \), is mild. Instead the main effect now comes from the different sound horizon. For a fixed today’s \( \omega_c \) the negatively interacting model has a smaller cold dark matter density at last scattering \( \omega_c(z_s) \) than the non-interacting model. The sound horizon \( r_s(z_{dec}) \) is proportional to \( k_{eq}^{-1} \) where \( k_{eq} \) is the wave number corresponding to the scale \( \lambda_{eq} \) that re-enters the horizon at matter-radiation equality. The smaller \( \omega_c(z) \) at early times means that the matter density exceeds the radiation energy density later than in the non-interacting case.
As small scales re-enter the Hubble horizon before the large scales, $\omega_{eq}$ (or $k_{eq}^{-1}$) and hence the sound horizon $r_s(z_{eq})$ will be larger in the negatively interacting case. Table A2 confirms these conclusions (compare $D_V$ and $r_s$ in Models 1 and 25). The positive interaction model behaves vice versa. Now we can explain also the bad fit to the CMB. The angular power spectrum is very sensitive to the dark matter density at last scattering $\omega(z_\ast)$ (or at the redshift of matter-radiation equality $z_{eq}$). As the negative interaction model has a small $\omega(z_\ast)$ and hence a small $z_{eq}$, the matter-radiation equality occurs very close to last scattering $z_\ast$. Therefore last scattering does not happen in the matter dominated era but around the transition from radiation domination to matter domination. This causes a large early integrated Sachs–Wolfe effect (eISW), which amplifies the first (and second) acoustic peaks. The angular power spectrum looks like that of a non-interacting model with a very small today’s $\omega_c$. The positive interaction model looks like a non-interacting model with a very high today’s $\omega_c$, i.e., the first and second acoustic peaks are vastly undershot (due to the early matter-radiation equality and hence a small eISW amplification). Therefore, in order to obtain a good fit to the CMB in the interacting model, we need to adjust today’s $\omega_c$ in such a way that $\omega_c(z_\ast)$, or rather $\alpha_{eq}$, matches the best-fitting non-interacting model. We have done this in Models 27 and 28; see Fig. 2 and Table A2. In the best-fitting non-interacting model (Model 1) today’s dark matter density is $\omega_c = 0.107$, whereas to obtain a good fit with a negative (positive) interaction of $\Gamma/H_0 = -0.3$ ($+0.3$) we require a larger $\omega_c = 0.137$ (smaller) $\omega_c = 0.080$. As the larger (smaller) dark matter density leads to a smaller (larger) $\Omega_{de0}$, the interacting model will now have a smaller (larger) angular diameter distance to last scattering $D_A(z_\ast)$. This would lead to all the acoustic peak structure shifting slightly to the left (right) from the WMAP data. As $D_A$ is proportional to $H_0^{-1}$, this mismatch can be corrected by decreasing (increasing) the value of $H_0$ so that we obtain roughly the same $D_A(z_\ast)$ and hence the same acoustic peak positions as in the non-interacting case. With a negative (positive) interaction of $\Gamma/H_0 = -0.3$ ($+0.3$), we require $H_0 = 56$ (66), while the best-fitting non-interacting model has $H_0 = 61\,\text{km}\,\text{s}^{-1}\text{Mpc}^{-1}$. (Note: $D_V$ and $r_s$ in Table A2 are reported in units $h^{-1}\text{Mpc}$. The interacting Models 27 and 28 have $r_s = 154\,\text{Mpc}$, which is exactly the same as for the non-interacting Model 1.) Fig. 2 and Table A2 show that after the above-described adjustments the strongly interacting $|\Gamma|/H_0 = 0.3$ Models 27 and 28 provide an excellent fit to the CMB acoustic peaks. In the high-$l$ ($l > 32$) region of the TT and all of the TE spectrum, the interacting models are totally indistinguishable from the non-interacting best-fitting Model 1. However, as the negatively interacting Model 27 has small $\Omega_{de0} = 0.49$ and hence also a smaller $\Omega_{de}$ in the recent past than the non-interacting model, the late integrated Sachs–Wolfe effect is suppressed, so there is less TT power at low multipoles. As the non-interacting model slightly over shoots the $C_{l}^{TT}$ spectrum at low multipoles, the negatively interacting model leads to a better fit here; see Fig. 2 upper left panel and the column $\chi^2_{TT}$ in Table A2 for Models 1 and 27. (Note: the $\chi^2_{TT}$ numbers are from Gibbs sampling of the actual CMB map, and the more negative the number is the better the fit is.) The positive interaction Model 28 has a larger $\Omega_{de}$ in the recent times than the non-interacting model, and hence gives rise to a large late ISW effect, and a poor fit to low multipoles in the TT spectrum.

The SN data cover the relatively recent past only and hence the small $\Omega_{de0} = 0.49$ in the negative interaction Model 27 leads to a poorer fit. The SN data indeed slightly favour more acceleration in the recent past and the positive interaction Model 28 ($\Omega_{de0} = 0.76$) has this property, leading to a better fit to SN than the non-interacting Model 1, which has $\Omega_{de0} = 0.65$: see Fig. 2 lower left panel and the column $\chi^2_{SN}$ in Table A2. For the same reason the negative interaction model fits the BAO data worse than the positive interaction model. Also the BAO data cover only the relatively recent past and favour more acceleration between redshifts $z = 0.20$ and $z = 0.35$ than the best-fitting non-interacting model provides.

Indeed already from Table A2 we can see these general trends. All the best-fitting interacting models (2, 14, 18, and 22) have negative $\Gamma$ and are slightly better fits to the CMB due to slightly better fit to low-$l$ CMB spectra. In general the best-fitting interacting models have indistinguishable $\chi^2_{SN}$ and $\chi^2_{BAO}$ from the best-fitting non-interacting models. The largest-$|\Gamma|$ models within $\Delta \chi^2 < 4$ from the best-fitting model (see Models 3, 4, 15, 16, 19, 20, 23, 24 in Table A2) always obey the following: a good-fit large negative interaction model is by about $\Delta \chi^2 = 1-3$ better fit to WMAP than a good-fit large positive interaction model, again due to the low-$l$ behaviour. However, a negative interaction model is always a worse fit to both SN and BAO data (due to too small $\Omega_{de}$ in the recent past).

The ISW effect in the temperature angular power spectrum is given by

$$
C_l^{ISW} = 4\pi \int_0^\infty \frac{k^3}{2\pi^2} \left\{ \int_0^{\tau_0} \left[ \left( \Psi'(\tau,k) - \Phi'(\tau,k) \right) \right] d\tau \right\}^2 \frac{dk}{k}, \tag{6}
$$

where $j_l$ is the spherical Bessel function and $\tau_{eq}(\tau,\tau_0) = \int_0^\tau \tau' \delta_c(\tau')d\tau'$ is the optical depth from $\tau$ to today ($\tau_0$). Note that at late times ($0 < z \lesssim 10$) we have $\Phi = -\Psi$, since the anisotropic stress vanishes. As it is the combination $\Psi' - \Phi'$ which defines the ISW effect, we show on the left panel of Fig. 3 the evolution of $\Psi - \Phi$ for the same models as in Fig. 2 i.e., Models 1 and 25–28 from Table A2. At high redshifts $z \gtrsim 10^4$, deep in the radiation era, the evolution in the interacting models is indistinguishable from the non-interacting model. If we keep all the other parameters fixed to the best-fitting non-interacting model, then a negative (positive) interaction leads to faster (slower) decay of the potential $\Psi - \Phi$ around the time of last scattering; compare the dashed blue (solid black) curves to the green curve on the left panel of Fig. 3. This matches to what we already explained about the early ISW effect: it is more (less) pronounced in the case of negative (positive) interaction, since the matter-radiation equality appears later (earlier) than in the non-interacting case. At late times, $0 \lesssim z \lesssim 10$, the interaction starts to modify the ISW source directly. The negative (positive) interaction leads to more gradual (steep) decay of $\Psi - \Phi$, and to a smaller (enhanced) late ISW effect.

If we adjust $\omega_c$ and $H_0$ (and hence $\Omega_{de0}$) so that we ob-
tain the same $z_{eq}$ as in the non-interacting case, and hence a perfect fit to the acoustic peaks in the data, the above-described effects on the late ISW effect become even more pronounced: compare the dot-dashed red (solid cyan) curves to the green curve on the left panel of Fig. 3. This is because with negative (positive) $\Gamma$ we need a smaller (larger) $\Omega_{\text{de}}$, and so the background effect on the gravitational potential is to reduce (increase) its decay rate. Now an interesting question arises: how much of the late ISW effect in the good-fit models comes from the different background, i.e. different $\Omega_{\text{de},0}$ compared to the non-interacting best-fitting model, and how much comes from the modified perturbation evolution equations. The right panel of Fig. 3 addresses this question. Blue dashed (black solid) curves show how the negative interaction Model 27 (positive interaction Model 28) would behave if we ignored the interaction in the perturbation equations. Interestingly, we would drastically overestimate the effect of interaction on the late ISW effect. In the perturbation equations, see equations (11–14) or (29–41) in the companion paper (Majerotto, Valiviita & Maartens 2009), there seems to be a term which partially cancels the effect of different background evolution. This is easiest to see in the longitudinal (conformal Newtonian) gauge where $B = 0 = E$. As the dark energy perturbations remain sub-dominant, the interaction terms in their evolution equations cannot be responsible for the difference. Moreover, in the CDM velocity equation explicit interaction term is completely missing. So the only perturbation equation where the interaction appears to have an effect is the CDM density contrast equation, which in the longitudinal gauge reads

$$\delta' = 3\psi' - a\Gamma \phi.$$  \hfill (7)

As long as the scale factor is small ($a \ll 1$) the evolution is like the non-interacting evolution, apart from the different evolution of the background, but in the later matter dominated era or dark energy dominated era, when $a$ starts to approach 1, the interaction starts to modify directly the way the CDM reflects gravitational potential wells. In this era there is an anisotropic stress, so $\phi = \psi$, and let us assume that $\psi > 0$. Then due to the background effect of dark energy, $\psi' < 0$. Now the effect of the $-a\Gamma \phi$ term is that if $\Gamma < 0$ ($> 0$), then the CDM density contrast decays slower (faster) than in the non-interacting case. This in turn feeds back into the evolution of $\psi$ via an Einstein equation (the general relativistic Poisson equation, equation (39) in the companion paper (Majerotto, Valiviita & Maartens 2009)). The effect is stronger the closer to 1 the scale factor is.

In the Newtonian gauge we can always neglect the dark energy perturbations, e.g. the total density contrast is $\delta = \delta_{\text{rho}}/\rho_{\text{tot}}$ at late times. However, in synchronous gauge we cannot do this for the velocity perturbation since $\theta_v = 0$. Indeed, at late times $\theta_v \approx \theta_{\text{de}}$. But the second Einstein equation is $k^2 \eta_{\nu} = 4\pi Ga^2 (\rho + p) \theta_{\text{tot}}$ – see e.g. equation (21b) in Ma & Bertschinger (1995) – and this is how the synchronous gauge metric perturbation $\eta_{\nu}$ is calculated in CAMB (Lewis et al. 2000). So in synchronous gauge the interaction in the perturbation equations enters the ISW effect via the interaction in the $\theta_{\text{de}}$ equation, (12) in the companion paper (Majerotto, Valiviita & Maartens 2009).

Note that it is difficult to go to very large positive in-
Figure 4. 2d marginalized likelihoods for the interacting model with only the WMAP, only the SN, and only the BAO data. The darker blue or red colours indicate 68% CL regions while the lighter blue or red colours indicate 95% CL regions with the SN or BAO data, respectively. The best-fits stand for the best-fitting models in the ranges shown in this figure. Therefore, here the BAO best-fitting model differs from the tabulated one which is at $\Gamma/H_0 = 2.92$; see Table A2.

Figure 5. 2d marginalized likelihoods for the interacting model with the WMAP, WMAP&SN, WMAP&BAO and WMAP&SN&BAO data.
interactions, since the larger the $\Gamma$, the larger $w_c$ one needs in order to avoid negative $\Omega_{de}$ in the past, i.e., to avoid the zero crossing of $\rho_{de}$ which causes the perturbation equations becoming singular at that moment, as discussed in Appendix A3. So we expect the large interaction models to fit the CMB data as well as the non-interacting model, with negative $\Gamma$ sightly favoured since this improves the fit in the low multipole region. Moreover, in marginalized likelihoods the negative interaction models will be favoured, since the $\rho_{de}$ zero-crossing problem means that there is much less volume in the allowed parameter space in the positive $\Gamma$ region than in the negative $\Gamma$ region; see Appendix A3. There will be a strong degeneracy between $\omega_c$ and $\Gamma$, which causes the perturbation equations becoming singular at that moment, as discussed in Appendix A3. So we expect the large interaction models to fit the CMB data as well as the non-interacting model, with negative $\Gamma$ sightly favoured since this improves the fit in the low multipole region. Moreover, in marginalized likelihoods the negative interaction models will be favoured, since the $\rho_{de}$ zero-crossing problem means that there is much less volume in the allowed parameter space in the positive $\Gamma$ region than in the negative $\Gamma$ region; see Appendix A3. There will be a strong degeneracy between $\omega_c$ and $\Gamma$, $H_0$ and $\Gamma$, and $\Omega_{de0}$ and $\Gamma$. When adding the other data (SN or BAO or SN&BAO) we expect most of the negative interaction models that fit the CMB alone well, to be excluded due to their very small $\Omega_{de}$ today and in the recent past.

\end{figure}

3 LIKELIHOODS

As predicted, due to the degeneracy between $\omega_c$ and $\Gamma/H_0$, the CMB data alone do not provide tight constraints on the interaction. The degeneracy is almost linear, $\omega_c \approx 0.107 - 0.1\Gamma/H_0$, according to Fig. 1 which shows 68% and 95% confidence level (CL) regions with WMAP, WMAP&ACBAR, and WMAP&SN&BAO data. As explained in the previous section, once $\omega_c$ (and $H_0$) are adjusted, the interacting model produces completely indistinguishable CMB angular power spectra at $l \gtrsim 32$. Therefore, combining WMAP (which reaches up to $l \sim 1000$) with ACBAR (which reaches $l \sim 2000$) does not help at all. Indeed, even with the forthcoming Planck data one will not be able to improve the constraints presented in Fig. 1 unless supplemented with some other non-CMB data. This is because the only signature from the interaction appears in the ISW region, and there the accuracy of CMB data is already now cosmic variance limited.

Furthermore, we see from Fig. 1 that according to the marginalized likelihoods with the CMB data, negative inter-
actions are strongly “favoured” over positive interactions. As explained in Appendix A3, this is partially due to a volume effect caused by shrinking of the allowed $w_e$ direction of parameter space for large positive interaction. In addition, positive interactions worsen the fit to the ISW region, while negative interactions improve it. According to Fig. 1, the 95% CL region of $\Gamma/H_0$ extends from -0.9 to +0.1. However, it should be noted that even stronger than -0.9 negative interactions would become allowed, if we lowered the lower bounds of two of our top-hat priors: $40 < H_0 < 100$, and $0 < \Omega_{de0} < 1$. This becomes evident later in the second and third panels of Fig. 5.

Adding SN and BAO data to the analysis leads to a more symmetric 95% CL region $-0.23 < \Gamma/H_0 < +0.15$, as seen in Fig. 4. In this case, the worse fit to ISW and the volume effect from $w_e$ in the case of positive interaction become cancelled by better fits to the SN and BAO data. In order to gain more insight into this, in some cases dangerous, competition between the CMB and other data, we compare in Fig. 4 selected 2d marginalized posterior likelihoods when using only WMAP or only SN or only BAO data.

The SN or BAO data alone do not significantly constrain any parameters of our model other than those shown in Fig. 4, i.e., they push $w_e$ down to $w_e \lesssim 0.15$, $\Omega_{de0}$ up to $0.65 \lesssim \Omega_{de0} \lesssim 0.90$, and $w_0$ down to $w_0 \sim 0.75$ at 68% CL. The non-interacting model ($\Gamma = 0$) is consistent with all three data sets (WMAP, SN, BAO). Most interestingly, the non-interacting model sits in the intersection of all three data sets so that there is no tension between them. As already noticed, there is a tension between CMB and SN or CMB and BAO in the negatively interacting models. This tension is most pronounced in the top right panel ($\Gamma, \Omega_{de0}$) of Fig. 4. However, the situation is not too bad since there is plenty of parameter space volume in the intersection of 95% CL regions of WMAP and SN or WMAP and BAO. Although the SN or BAO data do not put any direct constraints on the interaction (even $|\Gamma/H_0| \sim 3$ fits them well) the net effect of combining CMB with SN or BAO data is

![Figure 7](image-url). Comparison of 1d marginalized likelihoods for the interacting and non-interacting models with the WMAP and WMAP&SN data. The solid lines are for the non-interacting ($\Gamma = 0$) reference model.
to force $\Omega_{de0} \gtrsim 0.65$ and hence to cut away the large negative interaction models, leaving an almost symmetric region around $\Gamma = 0$. This effect is seen in the top left panel of Fig. 3 where we show 2d marginalized likelihoods from our MCMC runs for the interacting model with the WMAP data alone, the WMAP&SN, the WMAP&BAO, and the WMAP&SN&BAO data. The SN and BAO data are rather consistent with each other when constraining the interacting model. Therefore combining WMAP with either or both of them leads to very similar constraints, as seen in Fig. 5.

In Fig. 6 we show the 1d marginalized likelihoods for all of the primary MCMC parameters of our model and for two derived parameters: $\Omega_{de0}$ and the age of the universe. We note that WMAP combined with the BAO data prefers slightly larger today’s Hubble parameter $H_0$ and dark energy density $\Omega_{de0}$ than with the SN data. The CMB data alone favour negative interactions and thus require small $H_0$ and $\Omega_{de0}$. This corresponds to a very old universe as seen in the last panel of Fig. 5.

As mentioned above, from the 1d plot for $\Gamma/H_0$ in Fig. 8 the negative interaction seems more probable than the positive interaction. Indeed with the WMAP data (WMAP&SN&BAO data) 96.8% (77.6%) of models in our Markov Chains have a negative $\Gamma$, which means energy transfer from dark energy to dark matter. However, we should be cautious in claiming that the WMAP data (WMAP&SN&BAO data) favour energy transfer from dark energy to CDM at 96.8% CL (77.6% CL). It should again be stressed that this is partially the volume effect from the $w_\omega$ direction of the parameter space. Indeed, recently Pereira & Jesus (2009) claimed that with 93% probability the data – which in Pereira & Jesus (2009) were the background-based data only – favour decay of dark matter to dark energy. Now we have about the same probability in favour of energy transfer from the dark energy to dark matter. The message here is that, in addition to the volume effect, these claims are highly model dependent: Pereira & Jesus (2009) studied an interaction proportional to $\rho_{de}$ whereas our interaction is proportional to $\rho_{\omega}$. We summarize here our most stringent results for the interacting model by giving minimal 95% intervals [Hamann et al. 2007] from our MCMC run with WMAP&SN&BAO data: $\omega_b \in (0.0212, 0.0241)$, $\omega_c \in (0.859, 0.125)$, $H_0 \in (63, 70)$, $\tau \in (0.057, 0.133)$, $\Gamma/H_0 \in (-0.23, +0.15)$, $w_\omega \in (-0.80, -0.19)$, $w_\epsilon \in (-1.00, -0.63)$, $n_S \in (0.937, 1.002)$, $\ln(10^{10} A_S^2) \in (2.95, 3.14)$, $\Omega_{de0} \in (0.648, 0.767)$, Age $\in (13.6, 14.3)$ Gyr.

In Fig. 7 we compare the 1d marginalized likelihoods of the interacting model to the non-interacting reference model ($\Gamma = 0$). The key differences are: the interacting model leads to broader distributions of $\omega_\omega$, $H_0$ and $\Omega_{de0}$. This is due to the degeneracy between $\omega_\omega$ (or $H_0$ or $\Omega_{de0}$) and $\Gamma$. Moreover, $H_0$ is favoured by the interacting model. However, note again that this is partially a parameter space volume effect, since in our MCMC chains there are many more negative interaction models than positive interaction models, and the good-fit negative interaction models have small $H_0$.

Finally we note that $H_0$, both in the interacting and non-interacting cases, is smaller than in the ΛCDM model, where a typical result of a likelihood scan peaks around $H_0 = 72\,\text{km}\,\text{s}^{-1}\,\text{Mpc}^{-1}$. This is because we let $\omega_0$ (and $w_\omega$) vary, and there is a strong degeneracy (even if in the non-interacting case) between $H_0$ and $\omega_0$ (or $w_{de0}$). From Fig. 8 we see that a $\omega_0 = -1$ model prefers largest $H_0$ (and if we allowed $\omega_0 < -1$, even larger values of $H_0$ would be favoured).

### 4 ADDITIONAL CONSTRAINTS ON THE MODEL

In the two previous sections we have seen that any CMB data alone fail to constrain the interacting model, in particular with negative interaction, but the constraints from the SN or BAO data for the background dark energy density in the recent past cut out the strong interaction models with $\Gamma < 0$, as these models have very small $\Omega_{de0}$. In this section we briefly discuss some other data that could be used.

Most interestingly, as the interaction seems to affect the ISW effect only, accurate CMB – large-scale structure (LSS) cross-correlation data on the ISW effect (combined with other data sets such as CMB, SN and BAO) may turn out to set the most stringent constraints on the interaction. Firstly, the CMB–LSS cross-correlation data probe the evolution of $\Omega_{de}$ over time in the recent past. Secondly, as the interaction affects not only the background evolution, but directly the evolution of perturbations (in particular, the way that the evolution of the cold dark matter perturbation and gravitational potential are linked to each other) at redshifts probed by the ISW data, the ISW data may see the effects from the interaction most directly. We are working on this issue. While we were finalizing this paper, a work on other type of dark sector interaction appeared also suggesting that the interaction could be detected via its effects on the ISW signal [He et al. 2009]. Earlier Lee et al. (2006) discussed the modified ISW effect in an interacting quintessence model. However, they fixed all the other parameters to (or near to) the best-fitting to WMAP Lambda CDM model. Therefore, although mentioning the degeneracy between $\Omega_{de0}$ (or $\omega_\omega$) and the interaction rate elsewhere in their paper, they missed the degeneracy when finding con-
Observational constraints on an interacting dark energy model

Figure 9. Redshift evolution of $\sigma_8$ and matter power spectrum.

strains on the interaction rate with WMAP data, ending up with artificially tight constraints on the interaction with CMB data alone. This can be seen, for example, in the third panel of our Fig. [3] Had we fixed $\Omega_{\text{de}0}$ to 0.76, as [Lee et al. (2006)] did, our constraint on the interaction rate would be misleadingly tight: $-0.03 \lesssim \Gamma/H_0 \lesssim +0.005$. It should be noted that although adding SN or BAO or SNkBAO into the analysis forces $\Omega_{\text{de}0}$ (and $\omega_c$ and $H_0$) closer to the best-fitting (to WMAP) Lambda CDM model and hence leads to a similar kind of effect as fixing the parameters, letting the other parameters freely vary and consequently taking properly into account the degeneracy gives much looser constraint: $-0.23 < \Gamma/H_0 < +0.15$ with WMAP&SN&BAO. So fixing the other parameters would misleadingly give more than an order of magnitude smaller 95% interval in our case.

Other interesting data come form the galaxy-galaxy power spectrum which is a probe of the underlying theoretical matter power spectrum. However, we have decided not to use these data here, since the exact relation between the observed galaxy-galaxy power spectrum and matter power spectrum is not known (due to redshift space distortions, non-linearities, etc) and moreover we calculate the perturbation evolution in the linear regime only. Probably the interaction would affect non-linear structure formation [Baldi et al. 2008; Baldi 2009]. So at the moment it does not make sense to fit the shape of the (linear) matter power to the data. For similar reasons we do not consider weak-lensing data.

As the strongly interacting Models 27 and 28 in Table [A2] have very different recent-time evolution of matter and dark energy densities, the overall amplitude of the matter power is affected. This results in different $\sigma_8$ (root mean square mass fluctuation on $8h^{-1}$ Mpc scale) than in the non-interacting model. We find that today $\sigma_8(z = 0) = 0.598$, 0.628, 0.654 for Model 27 ($\Gamma/H_0 = -0.3$), Model 1 ($\Gamma = 0$), and Model 28 ($\Gamma/H_0 = +0.3$), respectively. Therefore, we predict that $\sigma_8$ measurements could rule out large negative interactions as they may lead to too small $\sigma_8$. On the left panel of Fig. [9] we show the redshift evolution of $\sigma_8$. We have normalized the curves for the interacting models to fit today’s $\sigma_8$ of the non-interacting model. For example, for the $\Gamma/H_0 = -0.3$ model $\sigma_8(z = 0)$ is smaller than in the non-interacting case, and towards the past it decreases even faster than in the non-interacting case. On the right panel of Fig. [9] we compare matter power spectra at redshifts $z = 0$ and $z = 2$ in the strongly interacting and non-interacting models. Small-scale (large $k$) shape is unaffected by the interaction, whereas large-scale (small $k$) shape (and amplitude) are affected significantly. Marginalizing analytically over the galaxy bias, the SDSS DR4 Luminous Red Galaxies sample [Tegmark et al. 2004; 2006] gives the best $\chi^2$ for the positive interaction and worst $\chi^2$ for the negative interaction, while the $\chi^2$ of the non-interacting model falls between these two. As the effect of adding the LSS data to the analysis seems to be very similar to the effect of adding BAO or SN, we expect that adding the LSS data would give more weight to the positive interactions and hence lead to even more symmetric and tighter probability distribution about $\Gamma = 0$ than with the CMB&SNkBAO data.

5 CONCLUSION

In the companion paper [Majerotto, Valiviita & Maartens 2009] we have presented, for the first time, a systematic derivation of initial conditions for perturbations in interacting dark matter – dark energy fluid models deep in the radiation dominated era. These initial conditions are essential for studying the further evolution of perturbations up to today’s observables. We have focused on the interaction $Q_c = -\Gamma \rho_c (1 + \delta_c) u_c^2$, where $\Gamma$ is a constant which has the same dimension as the Hubble parameter $H$; see Eqs. [1] and [2]. In our previous work [Valiviita et al. 2008] we showed that if the equation of state parameter for dark energy is $-1 < w_{\text{de}} < -4/5$ in the radiation or matter dominated era, the model suffers from a serious non-adiabatic insta-
bility. However, in this paper (and in the companion paper (Majerotto, Valiviita & Maartens 2009)) we have shown that the instability can easily be avoided, if we allow for suitably time-varying dark energy equation of state. Our worked out example is for the parametrization \( \omega_{de} = \omega_0 a + \omega_e (1 - a) \). With this parametrization, equations (11–14) from the companion paper (2), as well as the interacting perturbation evolution for interacting evolution equations for the background (1) and

We have modified publicly available CosmoMC (Lewis & Sugiyama 1996) which is valid if the matter scalings are the standard ones, \( \rho_b \propto a^{-3} \) and \( \rho_c \propto a^{-3} \). Firstly we need a different formula, as for BAO we want to integrate up to decoupling \( a_{dec} \), for which one has another fitting formula (Hu & Sugiyama 1996). Also this formula is valid only if \( \rho_b \propto a^{-3} \) and \( \rho_c \propto a^{-3} \). However, we know that this is not true for our case. Therefore we find \( a_{dec} \) numerically, and then calculate numerically

\[
rs(a) = \int_0^{a_{dec}} c_s(a)/a' da , \quad (A1)
\]

where \( c_s \) is the sound speed in the photon-baryon fluid and \( a_s \) is very accurately calculated from a fitting formula [Hu & Sugiyama 1996] which is valid if the matter scalings are the standard ones, \( \rho_b \propto a^{-3} \) and \( \rho_c \propto a^{-3} \). Firstly we need a different formula, as for BAO we want to integrate up to decoupling \( a_{dec} \), for which one has another fitting formula (Hu & Sugiyama 1996). Also this formula is valid only if \( \rho_b \propto a^{-3} \) and \( \rho_c \propto a^{-3} \). However, we know that this is not true for our case. Therefore we find \( a_{dec} \) numerically, and then calculate numerically

\[
rs(a_{dec}) = \int_0^{a_{dec}} c_s(a)/a' da \quad (A2)
\]

The defining equation of decoupling is [Hu & Sugiyama 1996]

\[
- \int_{\tau_0}^{\tau} R(\tau) \times opacity(\tau) d\tau = 1 , \quad (A3)
\]

where \( R = \frac{3}{2} \rho_b / \rho_c \). We numerically follow this integral from today toward past times \( \tau \) until the value 1 is reached. Then we record the value of the scale factor at this moment, name it \( a_{dec} \) and convert to a redshift \( z_{dec} = 1/a_{dec} - 1 \). Finally, to match the definitions in [Eisenstein et al. 2007] and [Percival et al. 2007] (from where we take the BAO data) we multiply the result by their “phenomenological” factor 0.96; \( z_{dec} = 0.96 z_{dec} \). We have verified that in the non-interacting case these definitions and our numerical routines lead to the same \( z_{dec} \) and \( rs(a_{dec}) \) as those given as a test case in [Percival et al. 2007].

A2 The parameters and their prior ranges

In the interacting model we have 9 primary MCMC parameters which we vary over wide ranges with uniform (flat) prior over their range: the physical baryon density today \( \omega_b = h^2 \Omega_{bh} \), the physical cold dark matter density today \( \omega_c = h^2 \Omega_{ch} \), the Hubble parameter today \( H_0 \), optical depth to reionization \( \tau_e \), the interaction \( \Gamma \) in units of today’s Hubble parameter, the early dark energy equation of state parameter \( w_e \), the dark energy equation of state parameter today \( \omega_0 \), scalar spectral index \( n_S \) of the primordial perturbations, and the amplitude of primordial perturbations \( A_S \) [we use log\((10^{10} A_S^2)\) as in the standard CosmoMC]. In the non-interacting reference model we have 8 free parameters as we keep \( \Gamma \) fixed to zero.

We exclude phantom models (\( \omega_{de} < -1 \)) as unphysical, and we focus on the following ranges

\[
-1 < \omega_0 < 0 , \quad -1 < w_e < 0.3 . \quad (A4)
\]

It should be noted that the CMB data actually exclude all
Observational constraints on an interacting dark energy model

Figure A1. The $w_e$ volume effect. The circles show samples from our MCMC run with the WMAP&BAO data. The colour scale indicates the value of $w_0$ for each sample.

### A3 Positive $\Gamma$ and zero-crossing of $\rho_{de}$

There is one additional complication in studying the interacting model and interpreting the marginalized posterior likelihoods. As pointed out in Valiviita et al. (2008), in the case of constant $w_{de}$, any positive interaction $\Gamma/H_0 > 0$ would lead to a zero crossing of $\rho_{de}$, or in other words $\Omega_{de}$. This means that starting the background calculation from today’s positive value, say $\Omega_{de,0} \sim 0.7$, and integrating backward in time, at some moment $\tau_{de,zc}$ in the past $\Omega_{de}(\tau)$ crosses zero and becomes negative for $\tau < \tau_{de,zc}$. While we lack deep understanding of the nature of dark energy we might even accept this possibility. However, the perturbation equations (11) and (12) in the companion paper (Majerotto, Valiviita & Maartens 2009), have the dark energy density in the denominator, and therefore become singular when adding the SZ templates to the high-$l$ part of the TT angular power spectrum. We also restrict the analysis to positive dark energy densities today, i.e., apply a top-hat prior $\Omega_{de0} > 0$. As we study spatially flat models, the matter density today is $\Omega_{m0} = 1 - \Omega_{de0}$.

In Table A1 we list some of the above-mentioned parameters as well as other symbols used in this paper.

As discussed in Valiviita et al. (2008), $|\Gamma/H_0| \gg 1$ would conflict with the data. We find that a reasonable range is $\Gamma/H_0 \in (-4, +4)$. The ranges of other remaining primary MCMC parameters are: $\omega_b \in (0.005, 0.1)$, $w_e \in (0.01, 0.99)$, $H_0 \in (40, 100)$, $\tau \in (0.01, 0.4)$, $n_S \in (0.5, 1.5)$, $\ln(10^{10}A_S^2) \in (2.7, 4.0)$. Finally, we have an amplitude of the SZ template in CosmoMC, $A_{SZ} \in (0, 2)$, which is used

When adding the SZ templates to the high-$l$ part of the TT angular power spectrum. We also restrict the analysis to positive dark energy densities today, i.e., apply a top-hat prior $\Omega_{de0} > 0$. As we study spatially flat models, the matter density today is $\Omega_{m0} = 1 - \Omega_{de0}$.

In Table A1 we list some of the above-mentioned parameters as well as other symbols used in this paper.

A3 Positive $\Gamma$ and zero-crossing of $\rho_{de}$

There is one additional complication in studying the interacting model and interpreting the marginalized posterior likelihoods. As pointed out in Valiviita et al. (2008), in the case of constant $w_{de}$, any positive interaction $\Gamma/H_0 > 0$ would lead to a zero crossing of $\rho_{de}$, or in other words $\Omega_{de}$. This means that starting the background calculation from today’s positive value, say $\Omega_{de0} \sim 0.7$, and integrating backward in time, at some moment $\tau_{de,zc}$ in the past $\Omega_{de}(\tau)$ crosses zero and becomes negative for $\tau < \tau_{de,zc}$. While we lack deep understanding of the nature of dark energy we might even accept this possibility. However, the perturbation equations (11) and (12) in the companion paper (Majerotto, Valiviita & Maartens 2009), have the dark energy density in the denominator, and therefore become singular

When adding the SZ templates to the high-$l$ part of the TT angular power spectrum. We also restrict the analysis to positive dark energy densities today, i.e., apply a top-hat prior $\Omega_{de0} > 0$. As we study spatially flat models, the matter density today is $\Omega_{m0} = 1 - \Omega_{de0}$.

In Table A1 we list some of the above-mentioned parameters as well as other symbols used in this paper.

A3 Positive $\Gamma$ and zero-crossing of $\rho_{de}$

There is one additional complication in studying the interacting model and interpreting the marginalized posterior likelihoods. As pointed out in Valiviita et al. (2008), in the case of constant $w_{de}$, any positive interaction $\Gamma/H_0 > 0$ would lead to a zero crossing of $\rho_{de}$, or in other words $\Omega_{de}$. This means that starting the background calculation from today’s positive value, say $\Omega_{de0} \sim 0.7$, and integrating backward in time, at some moment $\tau_{de,zc}$ in the past $\Omega_{de}(\tau)$ crosses zero and becomes negative for $\tau < \tau_{de,zc}$. While we lack deep understanding of the nature of dark energy we might even accept this possibility. However, the perturbation equations (11) and (12) in the companion paper (Majerotto, Valiviita & Maartens 2009), have the dark energy density in the denominator, and therefore become singular

When adding the SZ templates to the high-$l$ part of the TT angular power spectrum. We also restrict the analysis to positive dark energy densities today, i.e., apply a top-hat prior $\Omega_{de0} > 0$. As we study spatially flat models, the matter density today is $\Omega_{m0} = 1 - \Omega_{de0}$.

In Table A1 we list some of the above-mentioned parameters as well as other symbols used in this paper.

A3 Positive $\Gamma$ and zero-crossing of $\rho_{de}$

There is one additional complication in studying the interacting model and interpreting the marginalized posterior likelihoods. As pointed out in Valiviita et al. (2008), in the case of constant $w_{de}$, any positive interaction $\Gamma/H_0 > 0$ would lead to a zero crossing of $\rho_{de}$, or in other words $\Omega_{de}$. This means that starting the background calculation from today’s positive value, say $\Omega_{de0} \sim 0.7$, and integrating backward in time, at some moment $\tau_{de,zc}$ in the past $\Omega_{de}(\tau)$ crosses zero and becomes negative for $\tau < \tau_{de,zc}$. While we lack deep understanding of the nature of dark energy we might even accept this possibility. However, the perturbation equations (11) and (12) in the companion paper (Majerotto, Valiviita & Maartens 2009), have the dark energy density in the denominator, and therefore become singular

When adding the SZ templates to the high-$l$ part of the TT angular power spectrum. We also restrict the analysis to positive dark energy densities today, i.e., apply a top-hat prior $\Omega_{de0} > 0$. As we study spatially flat models, the matter density today is $\Omega_{m0} = 1 - \Omega_{de0}$.

In Table A1 we list some of the above-mentioned parameters as well as other symbols used in this paper.
at the moment $\tau_{de,ec}$. For this reason, as discussed in Valiviita et al. (2008), all positive interactions with our type of interaction are ruled out if $w_{de}$ is constant. However, the situation changes dramatically when we allow for time varying $w_{de}$. In viable models $w_{de}$ today is close to $-1$ and then, as $-4/5 < w_e < 1/3$, going towards the past makes $w_{de}$ less negative or even positive. If $w_{de}$ becomes less negative before the moment $\tau_{de,ec}$, then the zero crossing can actually be avoided. It turns out that the threshold value, $w_{e,th}$, depends mildly on all the background density parameters and strongly on the interaction $\Gamma/H_0$ and, of course, $w_0$. The larger positive interaction we have, the larger $w_{e,th}$ we need in order to avoid the zero-crossing of $\rho_{de}$, and hence the singularity of the perturbation equations. This means that for a given positive $\Gamma$ (and the background parameters) all the models with $w_e < w_{e,th}(\Gamma/H_0, w_0)$ will be missing from our Markov chains. There is no similar “top-hat cut-off” of models for negative $\Gamma$. This represents a difficulty in interpreting the marginalized posterior likelihoods. Let us assume a completely symmetric situation with respect to $\Gamma = 0$. Then without the cut-off, we would find 50% of the area under our 1d marginalized posterior for $\Gamma = 0$. However, with the cut-off unavoidably in operation, even if both positive and negative $\Gamma$ models with $w_e > w_{e,th}(\Gamma/H_0, w_0)$ lead to exactly the same theoretical predictions (and hence to the same likelihoods), on the positive $\Gamma$ side the marginalization integral over $w_e$ collects only the volume $1/3 - w_{e,th}(\Gamma/H_0, w_0) \ll 1.133$, while on the negative $\Gamma$ side the volume factor is $1/3 - (-4/5) = 1.133$. The volume factor in the positive $\Gamma$ side becomes smaller the larger $\Gamma$ is. Therefore, even in this hypothetical “symmetric” situation, the marginalized likelihood for $\Gamma$ would show a strong “preference” for a negative interaction.

We demonstrate the cut-off effect in Fig. A1 which shows samples from our Markov chains from the run with WMAP&BAO data. For example, if $\Gamma/H_0 = -0.1$, then the good-fit region is $-0.75 < w_e < -0.2$, whereas for $\Gamma/H_0 = +0.1$, all the models $-0.8 < w_e < -0.45$ are forbidden because of the zero crossing of $\rho_{de}$. Fig. A1 shows also that when $w_e$ is very negative, we can to some extent compensate this with less negative $w_0$, as mentioned above.

With negative values of $\Gamma$ we see in Fig. A1 milder, cut-off of models between $-4/5 < w_e < -2/3$. Asymptotically with large interactions this cut-off line approaches $w_e = -2/3$. From Table 1 on page 3 we can find an explanation for this behaviour. Although perturbations in the radiation era behave well and we can set adiabatic initial conditions, there is a rapidly growing non-adiabatic mode in the matter era, if $-4/5 < w_e < -2/3$. This mode kicks in faster the stronger the interaction is. In addition, this mode grows the faster the further away from $w_e = -2/3$ we are. Therefore, some models with small interaction rate and/or $w_e$ close enough to $-2/3$ survive.

### APPENDIX B: BEST-FITTING MODELS

We have collected in Table A2 $\chi^2$s and parameters of the best-fitting models from our MCMC runs with various data sets (Models 1–24), as well as the example models discussed in Sec. 2 and Figs. 2, 3 and 4 (Models 25–28). It should be noted that Models 6 and 10 (with $w_e < -0.8$) would be excluded by the CMB data due to the blow-up of perturbations, but since the SN and BAO data probe background quantities only, these models fit them well. As the $\chi^2$ is rather insensitive to $w_e$ almost equally well-fitting models with $w_e > -0.8$ do exist in our chains.
Observational constraints on an interacting dark energy model

Table A2. The χ^2s and parameters of the best-fitting model from each of our 6 MCMC runs for the non-interacting model (Γ = 0) and from our MCMC runs for the interacting model (Γ ≠ 0). The rows "neg. Γ" and "pos. Γ" show the models with largest |Γ| (found in our MCMC chains) such that χ^2 is within 4 (∼2σ if the likelihood was Gaussian) from the corresponding best-fitting model.

| Model      | Data       | χ^2  | χ^2VMPA  | χ^2f<sub>L<sub>  | χ^2TT  | χ^2TT  | χ^2SN  | χ^2BAO |
|------------|------------|------|----------|----------------|--------|--------|--------|--------|
| 1          | best Γ=0   | WMAP | 2660.4   | 2660.4    | 1221.5 | 1023.5 | -11.3  | 311.4  |
| 2          | best Γ≠0   | WMAP | 2659.5   | 2659.5    | 1221.5 | 1022.8 | -11.6  | 368.2  |
| 3          | neg. Γ     | WMAP | 2662.6   | 2662.6    | 1222.0 | 1024.9 | -11.1  | 389.4  |
| 4          | pos. Γ     | WMAP | 2663.4   | 2663.4    | 1222.2 | 1024.9 | -11.0  | 316.1  |
| 5          | best Γ=0   | SN   | 307.6    | -         | -       | -       | -       | 307.6  |
| 6          | best Γ≠0   | SN   | 306.5    | -         | -       | -       | -       | 306.5  |
| 7          | best Γ=0   | BAO  | 3.3      | -         | -       | -       | -       | 334.9  |
| 8          | best Γ≠0   | BAO  | 2.1      | -         | -       | -       | -       | 363.7  |

Other models appearing in the figures for phenomenological considerations:

| Model      | Data       | χ^2  | χ^2VMPA  | χ^2f<sub>L<sub>  | χ^2TT  | χ^2TT  | χ^2SN  | χ^2BAO |
|------------|------------|------|----------|----------------|--------|--------|--------|--------|
| 25         | As Model 1, but Γ/H_0 = -0.3 | WMAP & SN | 2968.7 | 2660.7    | 1222.2 | 1023.6 | -10.5  | 308.2  |
| 26         | As Model 1, but Γ/H_0 = +0.3 | WMAP & SN | 2968.4 | 2660.3    | 1221.0 | 1024.1 | -11.9  | 308.1  |
| 27         | As 25, but ω_c (Ω_m) & H_0 adjusted | WMAP & SN | 2972.1 | 2660.8    | 1222.2 | 1023.6 | -11.9  | 311.3  |
| 28         | As 26, but ω_c (Ω_m) & H_0 adjusted | WMAP & SN | 2971.9 | 2663.9    | 1222.6 | 1024.6 | -10.6  | 308.0  |

Table A2 - continued The cosmological parameters of the best-fitting models. Today’s Hubble parameter H_0 is in units km s^{-1} Mpc^{-1}, the age of the universe is given in Giga years, the distance measure D_v at redshifts z = 0.20 and z = 0.35 as well as the sound horizon at decoupling, r_s, are in units of h^{-1} Mpc, where h is defined by H_0 = h km s^{-1} Mpc^{-1}. Ampl. denotes the primordial perturbation amplitude, indeed ln(10^{10} A_s^2).
