Dependency Graph Approach for Multiprocessor Real-Time Synchronization

Jian-Jia Chen, Georg von der Brüggen, Junjie Shi and Niklas Ueter
TU Dortmund University, Germany

Abstract—Over the years, many multiprocessor locking protocols have been designed and analyzed. However, the performance of these protocols highly depends on how the tasks are partitioned and prioritized and how the resources are shared locally and globally. This paper answers a few fundamental questions when real-time tasks share resources in multiprocessor systems. We explore the fundamental difficulty of the multiprocessor synchronization problem and show that a very simplified version of this problem is \(NP\)-hard in the strong sense regardless of the number of processors and the underlying scheduling paradigm. Therefore, the allowance of preemption or migration does not reduce the computational complexity. For the positive side, we develop a dependency-graph approach, that is specifically useful for frame-

computational complexity. For the positive side, we develop a dependency-graph approach, that is specifically useful for frame-

processors and the underlying scheduling paradigm. Therefore,

\(N\)

is

\(\text{the allowance of preemption or migration does not reduce the}

processors and the underlying scheduling paradigm. Therefore,

\(N\)

is

\(\text{the allowance of preemption or migration does not reduce the}

processors and the underlying scheduling paradigm. Therefore,

\(N\)

is

\(\text{the allowance of preemption or migration does not reduce the}

processors and the underlying scheduling paradigm. Therefore,

\(N\)

is

\(\text{the allowance of preemption or migration does not reduce the}

processors and the underlying scheduling paradigm. Therefore,

\(N\)

is

\(\text{the allowance of preemption or migration does not reduce the}

processors and the underlying scheduling paradigm. Therefore,

\(N\)

is

\(\text{the allowance of preemption or migration does not reduce the}

processors and the underlying scheduling paradigm. Therefore,

\(N\)

is

\(\text{the allowance of preemption or migration does not reduce the}

processors and the underlying scheduling paradigm. Therefore,
that uses an advanced cost heuristic algorithm to split a task group when the entire group fails to be assigned on one processor. In subsequent work, Hsiu et al. [23] proposed a dedicated-core framework to separate the execution of critical sections and normal sections, and employed a priority-based mechanism for resource sharing, such that each request can be blocked by at most one lower-priority request. Wied and Brandenburg [49] proposed a greedy slacker partitioning heuristic in the presence of spin locks. The resource-oriented partitioned (ROP) scheduling was proposed by Huang et al. [24] in 2016 and later refined by von der Brüggen et al. [44] with release enforcement for a special case.

For priority assignment, most of the results in the literature use rate-monotonic (RM) or earliest-deadline-first (EDF) scheduling. To the best of our knowledge, the priority assignment for systems with shared resources has only been seriously explored in a small numbers of papers, e.g., relative deadline assignment under release enforcement in [19], priority assignment for spinning [1], reasonable priority assignments under global scheduling [17], and the optimal priority assignment used in the greedy slack algorithm in [49]. However, no theoretical evidence has been provided to quantify the non-optimality of the above heuristics.

Although many multiprocessor locking protocols have been proposed in the literature, there are a few unsolved fundamental questions when real-time tasks share resources (via locking mechanisms) in multiprocessor systems:

- What is the fundamental difficulty?
- What is the performance gap of partitioned, semi-partitioned, and global scheduling?
- Is it always beneficial to prioritize critical sections?

To answer the above questions, we focus on the simplest and the most basic setting: all tasks have the same period and release their jobs always at the same time, so-called frame-based real-time task systems, and are scheduled on $M$ identical (homogeneous) processors. Specifically, we assume that each critical section is non-nested and is guarded by only one binary semaphore or one mutex lock.

**Contribution:** Our contributions are as follows:

- We show that finding a schedule of the tasks to meet the given common deadline is $NP$-hard in the strong sense regardless of the number of processors $M$ in the system. Therefore, there is no polynomial-time approximation algorithm that can bound the allocated number of processors to meet the given deadline. Moreover, the $NP$-hardness holds under any scheduling paradigm. Therefore, the allowance of preemption or migration does not reduce the computational complexity.

- We propose a dependency graph approach for multiprocessor synchronization, which consists of two steps: 1) the construction of a directed acyclic graph (DAG), and 2) the scheduling of this DAG. We prove that for minimizing the makespan the lower bound of the approximation ratio of such an approach is at least $2 - \frac{1}{M}$ under any scheduling paradigm and $2 - \frac{1}{M}$ under partitioned or semi-partitioned scheduling.

- We demonstrate how existing results in the literature of uniprocessor non-preemptive scheduling can be adopted to construct the DAG in the first step of the dependency graph approach when each task has only one critical section. This results in several polynomial-time scheduling algorithms with different constant approximation bounds for minimizing the makespan. Specifically, the best approximation developed is a polynomial-time approximation scheme with an approximation ratio of $2 + \epsilon - \frac{1+\epsilon}{M}$ for any $\epsilon > 0$ under semi-partitioned scheduling strategies. We further discuss methodologies and tradeoffs of preemptive against non-preemptive scheduling algorithms and partitioned against semi-partitioned scheduling algorithms.

- We also implemented the dependency graph approach as a prototype in LITMUSRT [8], [13]. The experimental results show that the overhead is almost the same as the state-of-the-art multiprocessor locking protocols. Moreover, we also provide extensive numerical evaluations, which demonstrate the performance of the proposed approach under different scheduling constraints. Comparing to the state-of-the-art resource-oriented partitioned (ROP) scheduling, our approach shows significant improvement.

## 2 System Model

### 2.1 Task Model

In this paper, we will implicitly consider frame-based real-time task systems to be scheduled on $M$ identical (homogeneous) processors. The given tasks release their jobs at the same time and have the same period and relative deadline. Our studied problem is the task synchronization problem where all tasks have exactly one (not nested) critical section, denoted as TS-OCS. Specifically, each task $\tau_i$ releases a job (at time $0$ for notational brevity) with the following properties:

- $C_{i,1}$ is the execution time of the first non-critical section of the job.
- $A_{i,1}$ is the execution time of the (first) critical section of the job, in which a binary semaphore or a mutex $\sigma(\tau_{i,1})$ is used to control the access of the critical section.
- $C_{i,2}$ is the execution time of the second non-critical section of the job.

A subjob is a critical section or a non-critical section. Therefore, there are three subjobs of a job of task $\tau_i$. We assume the task set $T$ is given and that the deadline is either implicit, i.e., identical to the period, or constrained, i.e., smaller than the period. The cardinality of a set $X$ is $|X|$. We also make the following assumptions:

- For each task $\tau_i$ in $T$, $C_{i,1} \geq 0$, $C_{i,2} \geq 0$, and $A_{i,1} \geq 0$.
- The execution of the critical sections guarded by one binary semaphore $s$ must be sequentially executed under a total order. That is, if two tasks share the same semaphore, their critical sections must be executed one after another without any interleaving.
- The execution of a job cannot be parallelized, i.e., a job must be sequentially executed in the order of $C_{i,1}, A_{i,1}, C_{i,2}$.
- There are in total $\geq 1$ binary semaphores.

The paper will implicitly focus on the above task model. In Section 8 we will explain how the algorithms in this paper can be extended to periodic task systems under certain conditions.
2.2 Scheduling Strategies

Here, we define scheduling strategies and the properties of a schedule for a frame-based real-time task system. Note that the terminologies used here are limited to the scenario where each task in T releases only one job at time 0. Therefore, we will use the term jobs and tasks interchangeably.

A schedule is an assignment of the given jobs (tasks) to one of the M identical processors, such that each job is executed (not necessarily consecutively) until completion. A schedule for T can be defined as a function $\rho : \mathbb{R} \times M \rightarrow \mathcal{U} \cup \{\perp\}$, where $\rho(t,m) = \tau_j$ denotes that the job of task $\tau_j$ is executed at time $t$ on processor $m$, and $\rho(t,m) = \perp$ denotes that processor $m$ is idle at time $t$. We assume that a job has to be sequentially executed, i.e., intra-task parallelism is not possible. Therefore, it is not feasible to run a job in parallel on two processors, i.e., $\rho(t,m) \neq \rho(t,m')$ for any $m \neq m'$ if $\rho(t,m) \neq \perp$.

Some other constraints may also be introduced. A schedule is non-preemptive if a job cannot be preempted by any other job, i.e., there is only one interval with $\rho(t,m) = \tau_j$ on processor $m$ for each task $\tau_j$ in T. A schedule is preemptive if a job can be preempted, i.e., more than one interval with $\rho(t,m) = \tau_j$ for any task $\tau_j$ in T on processor $m$ is allowed.

For a partitioned schedule, a job has to be executed on one processor. That is, there is exactly one processor $m$ with $\rho(t,m) = \tau_j$ for every task $\tau_j$ in T. Such a schedule can be preemptive or non-preemptive. For a global schedule, a job can be arbitrarily executed on any of the M processors at any time point. That is, it is possible that $\rho(t,m) = \tau_j$ and $\rho(t',m') = \tau_j$ for $m \neq m'$ and $t \neq t'$. By definition, a global schedule is preemptive (for frame-based real-time task systems) in our model. For a semi-partitioned schedule, a subjob (either a critical section or a non-critical section) has to be executed on one processor. Such a semi-partitioned schedule can be preemptive or non-preemptive.

Based on the above definitions, a partitioned schedule is also a semi-partitioned schedule, and a semi-partitioned schedule is also a global schedule.

2.3 Scheduling Theory

In the rich literature of scheduling theory, one specific objective is to minimize the completion time of the jobs, called makespan. For frame-based real-time task systems, if the makespan of the jobs released at time 0 is no more than the relative deadline, then the task set can be feasibly scheduled to meet the deadline. We state the makespan problem for TS-OCS that is studied here as follows:

**Definition 1:** The TS-OCS Makespan Problem: We are given M identical (homogeneous) processors. There are N tasks arriving at time 0. Each task is given by $\{C_{i,1}, A_{i,1}, C_{i,2}\}$ and has at most one critical section, guarded by one binary semaphore. The objective is to find a schedule that minimizes the makespan.

Alternatively, we can also investigate the bin packing version of the problem, i.e., minimizing the number of allocated processors to meet a given common deadline $D$.

**Definition 2:** The TS-OCS Bin Packing Problem: We are given identical (homogeneous) processors. There are N tasks arriving at time 0 with a common deadline $D$. Each task is given by $\{C_{i,1}, A_{i,1}, C_{i,2}\}$ and has at most one critical section, guarded by one binary semaphore. The objective is to find a schedule to meet the deadline with the minimum number of allocated processors.

Essentially, the decision versions of the makespan and the bin packing problems are identical:

**Definition 3:** The TS-OCS Schedulability Problem: We are given M identical (homogeneous) processors. There are N tasks arriving at time 0 with a common deadline $D$. Each task is given by $\{C_{i,1}, A_{i,1}, C_{i,2}\}$ and has at most one critical section, guarded by one binary semaphore. The objective is to find a schedule to meet the deadline by using the M processors.

In the domain of scheduling theory, a scheduling problem is described by a triplet Field$_1$|Field$_2$|Field$_3$.

- Field$_1$: describes the machine environment.
- Field$_2$: specifies the processing characteristics and constraints.
- Field$_3$: presents the objective to be optimized.

For example, the scheduling problem $1|r_j|L_{\text{max}}$, deals with a uniprocessor system, in which the input is a set of jobs with different release times and different absolute deadlines, and the objective is derive a non-preemptive schedule which minimizes the maximum lateness. The scheduling problem $P||C_{\text{max}}$ deals with a homogeneous multiprocessor system, in which the input is a set of jobs with the same release times, and the objective is derive a partitioned schedule which minimizes the makespan.

2.4 Approximation Metrics

Since many scheduling problems are $NP$-hard in the strong sense, polynomial-time approximation algorithms are often used. In the realm of real-time systems, there are two widely adopted metrics:

The Approximation Ratio compares the resulting objectives of (i) scheduling algorithm $\mathcal{A}$ and (ii) an optimal algorithm when scheduling any given task set. Formally, an algorithm $\mathcal{A}$ for the makespan problem (i.e., Definition 1) has an approximation ratio $\alpha \geq 1$, if given any task set $T$, the resulting makespan is at most $\alpha C_{\text{max}}$ on $M$ processors, where $C_{\text{max}}$ is the minimum (optimal) makespan to schedule T on M processors. An algorithm $\mathcal{A}$ for the bin packing problem (i.e., Definition 2) has an approximation ratio $\alpha \geq 1$, if given any task set $T$, it can find a schedule of $T$ on $\alpha M^*$ processors to meet the common deadline, where $M^*$ is the minimum

---

Note that the deadline is never larger than the period in our setting.
(optimal) number of processors required to feasibly schedule \( T \).

The Speedup Factor [26], [36] of a scheduling algorithm \( A \) indicates the factor \( \alpha \geq 1 \) by which the overall speed of a system would need to be increased so that the scheduling algorithm \( A \) always derives a feasible schedule to meet the deadline, provided that there exists one at the original speed. This is used for the problem in Definition 3.

We note that an algorithm that has an approximation ratio \( \alpha \) for the makespan problem in Definition 1 also has a speedup factor \( \alpha \) for the schedulability problem in Definition 3.

3 Dependency Graph Approach for Multiprocessor Synchronization

To handle the studied makespan problem in Definition 1 we propose a **Dependency Graph Approach**, which involves two steps:

- In the first step, a directed graph \( G = (V, E) \) is constructed. A subjob (i.e., a critical section or a non-critical section) is a vertex in \( V \). The subjob \( C_{1,1} \) is a predecessor of the subjob \( A_{1,1} \). The subjob \( A_{1,1} \) is a predecessor of the subjob \( C_{1,2} \). If two jobs of \( \tau_1 \) and \( \tau_2 \) share the same binary semaphore, i.e., \( \sigma(\tau_1,1) = \sigma(\tau_2,1) \), then either the subjob \( A_{1,1} \) is the predecessor of that of \( A_{1,1} \) or the subjob \( A_{1,1} \) is the predecessor of that of \( A_{1,1} \). All the critical sections guarded by a binary semaphore form a chain in \( G \), i.e., the critical sections of the binary semaphore follow a total order. Therefore, we have the following properties in set \( E \):
  - The two directed edges \((C_{1,1}, A_{1,1})\) and \((A_{1,1}, C_{1,2})\) are in \( E \).
  - Suppose that \( T_k \) is the set of the tasks which require the same binary semaphore \( s_k \). Then, the \([T_k]\) tasks in \( T_k \) follow a certain total order \( \pi \) such that \((A_{1,1}, A_{1,1})\) is a directed edge in \( E \) when \( \pi(\tau_1) = \pi(\tau_2) - 1 \).

Fig. 1 provides an example for a task dependency graph with one binary semaphore. Since there are \( z \) binary semaphores in the task set, the task dependency graph \( G \) has in total \( z \) connected subgraphs, denoted as \( G_1, G_2, \ldots, G_z \). In each connected subgraph \( G_i \), the corresponding critical sections of the tasks that request critical sections guarded by the same semaphore form a chain and have to be executed sequentially. For example, in Fig. 1, the dependency graph forces the scheduler to execute the critical section \( A_{1,1} \) prior to any of the other three critical sections.

- In the second step, a corresponding schedule of \( G \) on \( M \) processors is generated. The schedule can be based on system’s restrictions or user’s preferences, i.e., either preemptive or non-preemptive schedules, either global, semi-partitioned, or partitioned schedules.

In the dependency graph approach, the second step has been widely studied in scheduling theory. That is, a solution of the problem \( \min_{\tau \in T} \max_{i \in [1, M]} \left( \frac{C_i}{\tau} \right) \) results in a semi-partitioned schedule, since the dependency graph is constructed by considering a critical section or a non-critical section as a subjob. Moreover, a solution of the problem \( \min_{\tau \in T} \max_{i \in [1, M]} \left( \frac{C_i}{\tau} \right) \) results in a global schedule. For deriving a partitioned schedule, we can force the subjobs generated by a job to be tied to one processor. That is, \( \min_{\tau \in T} \max_{i \in [1, M]} \left( \frac{C_i}{\tau} \right) \) targets a partitioned non-preemptive schedule and \( \min_{\tau \in T} \max_{i \in [1, M]} \left( \frac{C_i}{\tau} \right) \) targets a partitioned preemptive schedule.

Therefore, the key issue is the construction of the dependency graph. An alternative view of the dependency graph approach is to build the dependency graph assuming a sufficient number of processors (i.e., using as many processors as possible) in the first step, and then the second step considers the constraint of the number of processors. Towards the first step, we need the following definition:

**Definition 4:** A critical path of a task dependency graph \( G \) is one of the longest paths of \( G \). The critical path length of \( G \) is denoted by \( len(G) \).

For the rest of this paper, we denote a dependency task graph of the input task set \( T \) that has the minimum critical path length as \( G^* \). Note that \( G^* \) is independent of \( M \).

**Lemma 1:** \( len(G^*) \) is the lower bound of the TS-OCS makespan problem for task set \( T \) on \( M \) processors.

**Proof:** This comes from the setting of the problem, i.e., each task \( \tau_i \) has only one critical section guarded by one binary semaphore, and the definition of the graph \( G^* \), i.e., using as many processors as possible.

**Definition 5:** A feasible schedule \( S(G) \) of a task dependency graph \( G \) respect to the precedence constraints defined in \( G \) and the specified scheduling requirement, e.g., being global/semi-partitioned/partitioned and preemptive/non-preemptive. \( L(S(G)) \) is the makespan of \( S(G) \).

With the above definitions, we can recap the objectives of the two steps in the dependency graph approach. In the first step, we would like to construct a dependency graph \( G \) to minimize \( len(G) \), and in the second step, we would like to construct a schedule \( S(G) \) to minimize \( L(S(G)) \).

We conclude this section by stating the following theorem:

**Theorem 1:** The optimal makespan of the TS-OCS makespan problem for \( T \) on \( M \) processors is at least

\[
\max \left\{ \sum_{\tau \in T} \frac{C_{i,1} + A_{i,1} + C_{i,2}}{M} \right\} len(G^*)
\]

(1)

where \( G^* \) is a dependency task graph of \( T \) that has the minimum critical path length.

**Proof:** The lower bound \( len(G^*) \) comes from Lemma 1 and the lower bound \( \sum_{\tau \in T} \frac{C_{i,1} + A_{i,1} + C_{i,2}}{M} \) is due to the pigeon
hole principle.

4 Computational Complexity and Lower Bounds

This section presents the computational complexity and lower bounds of approximation ratios of the dependency graph approach.

4.1 Computational Complexity

The following theorem shows that constructing $G^*$ is unfortunately $NP$-hard in the strong sense.

**Theorem 2:** Constructing a dependency task graph $G^*$ that has the minimum critical path length is $NP$-hard in the strong sense.

**Proof:** This theorem is proved by a reduction from the decision version of the scheduling problem $1|r_j|L_{max}$, i.e., uniprocessor non-preemptive scheduling, in which the objective is to minimize the maximum lateness assuming that each job $J_j$ in the given job set $J$ has its known processing time $p_j \geq 0$, arrival time $r_j \geq 0$, and absolute deadline $d_j$. This problem is $NP$-hard in the strong sense by a reduction from the 3-Partition problem \[^{[30]}\]. Suppose that the decision version of the scheduling problem $1|r_j|L_{max}$ is to validate whether there exists a schedule in which the finishing time of each job $J_j$ is no less than $d_j$.

Let $H$ be any positive integer greater than $\text{max}_{j \in J} d_j$. For each job $J_j$ in $J$, we construct a task $\tau_j$ with one critical section, where $C_{j,1}$ is set to $r_j$, $C_{j,2}$ is set to $H - d_j$, and $A_{j,1}$ is set to $p_j$. By the setting, $C_{j,1} \geq 0$, $C_{j,2} \geq 0$, and $A_{j,1} \geq 0$ for every constructed task $\tau_j$. The critical sections of all the constructed tasks are guarded by only one binary semaphore. Let the task set constructed above be $T$. The above input task set $T$ by definition is a feasible input task set for the one-critical-section task synchronization problem.

We now prove that there is a non-preemptive uniprocessor schedule for $J$ in which all the jobs can meet their deadlines if and only if there is a dependency task graph $G^*$ with a critical path length less than or equal to $H$ for the constructed task set $T$.

If part, i.e., $\text{len}(G^*) \leq H$ holds: Without loss of generality, we index the tasks in $T$ so that the critical section of $A_{i,1}$ is the immediate predecessor of the critical section $A_{i+1,1}$ in $G^*$, e.g., as in Fig. 3. Suppose that $G^*(\tau_i)$ is the subgraph of $G^*$ that consists of only the vertices representing $\{C_{k,1}, A_{k,1}, C_{k,2}\mid k = 1, 2, \ldots, i - 1\} \cup \{C_{i,1}, A_{i,1}\}$ and the corresponding edges. Let $f_i$ be the longest path in $G^*(\tau_i)$ that ends at the vertex representing $A_{i,1}$.

By definition, $f_1$ is $C_{1,1} + A_{1,1}$. Moreover, $f_i$ is $\max\{f_{i-1}, C_{i,1}\} + A_{i,1}$ for every task $\tau_i$ in $T$. Since $\text{len}(G^*) \leq H$ and $C_{i,2} = H - d_i$, we know that $f_i + C_{i,2} \leq H \Rightarrow f_i \leq d_i$ for every task $\tau_i$ in $T$.

We can now construct the uniprocessor non-preemptive schedule for $J$ by following the same execution order. Here, we index the jobs in $J$ corresponding to $T$. The finishing time of job $J_1$ is $r_1 + p_1 = C_{1,1} + A_{1,1} = f_1$. The finishing time of job $J_i$ is $\max\{f_{i-1}, r_i\} + p_i = \max\{f_{i-1}, C_{i,1}\} + A_{i,1} = f_i$.

This proves the if part.

**Only-If part,** i.e., there is a uniprocessor non-preemptive schedule in which all the deadlines of the jobs in $J$ are met: The proof for the if part can be reverted and the same arguments can be applied. Due to space limitation, we omit the details.

**Theorem 3:** The makespan problem with task synchronization for $T$ on $M$ processors is $NP$-hard in the strong sense even if $M$ is sufficiently large under any scheduling paradigm.

**Proof:** This comes directly from Theorem 2. Consider that there are $M \geq |T| + 1$ processors. The if-and-only-if proof in Theorem 2 can be extended by introducing a concrete schedule that executes the two non-critical sections of task $\tau_i$ on one processor $i$ and the critical section of task $\tau_i$ on processor $|T| + 1$.

Theorem 3 expresses the fundamental difficulty of the multiprocessor synchronization problem and shows that a very simplified version of this problem is $NP$-hard in the strong sense regardless of the number of processors and the underlying scheduling paradigm. Therefore, the allowance of preemption or migration does not reduce the computational complexity. The fundamental problem is the sequencing of the critical sections, which is independent from the underlying scheduling paradigm. Therefore, no matter what flexibility the scheduling algorithm has (unless aborting and restarting a critical section is allowed), the computational complexity remains $NP$-hard in the strong sense.

4.2 Remarks: Bin Packing

Although the focus of this paper is the makespan problem in Definition 1 and the schedulability problem in Definition 2, we also state the following theorems to explain the difficulty of the bin packing problem in Definition 2.

**Theorem 4:** Minimizing the number of processors for a given common deadline of $T$ with task synchronization for $T$ (i.e., Definition 2) is $NP$-hard in the strong sense under any scheduling paradigm.

**Proof:** As the decision problem is Definition 2, we reach the conclusion based on Theorem 2.

**Theorem 5:** There is no polynomial-time (approximation) algorithm to minimize the number of processors for a given common deadline of $T$ with task synchronization for $T$ under any scheduling paradigm unless $P = NP$.

**Proof:** This is based on Theorems 2 and 3. If such a polynomial-time algorithm exists, then the problem $1|r_j|L_{max}$ can be solved in polynomial time, which implies $P = NP$.

4.3 Lower Bounds

The dependency graph approach requires two steps. The following theorem shows that even if both steps are optimized, the resulting schedule for the makespan problem with task synchronization is not optimal and has an asymptotic lower bound 2 of the approximation ratio.

\[^{[1]}\] The same statement also holds for using $M = |T|$ processors, but the proof is more involved.
Theorem 6: The optimal schedule on $M$ identical processors for the dependency graph $G^*$ that has the minimum critical path length is not optimal for the $TS-OCS$ makespan problem and can have an approximation bound of at least

- $2 - \frac{2}{M} + \frac{1}{M^2}$ under any scheduling paradigm, and
- $2 - \frac{1}{M}$ under partitioned or semi-partitioned scheduling.

Proof: We prove this theorem by providing a concrete input instance as follows:

- Suppose that $M$ is a given integer with $M \geq 2$ and we have $N = M^2 - M + 1$ tasks.
- We assume a small positive number $\delta$ which is close to 0 and a number $Q$ which is much greater than $\delta$, i.e., $\frac{Q}{N} \gg \delta > 0$.
- All $N$ tasks have a critical section guarded by the same binary semaphore.
- Task $r_1$ has $C_{1,1} = \delta$, $A_{1,1} = Q - \frac{Q}{M}$, and $C_{1,2} = \frac{Q}{M} + N \delta$.
- Task $r_2$ has $C_{i,1} = \delta$, $A_{i,1} = \delta$, and $C_{i,2} = \frac{Q}{M}$ for $i = 2, 3, \ldots, N$.

We need to show that the optimal dependency graph of this input instance in fact leads to the specified bound. The proof is in Appendix.

5 Algorithms to Construct $G$

The key to success is to find $G^*$. Unfortunately, as shown in Theorem 2, finding $G^*$ is NP-hard in the strong sense. However, finding good approximations is possible. The problem to construct $G$ is called the dependency-graph construction problem. Here, instead of presenting new algorithms to find good approximations of $G^*$, we explain how to use the existing algorithms of the scheduling problem $1|r_j|L_{\text{max}}$ to derive good approximations of $G^*$.

It should be first noted that the problem $1|r_j|L_{\text{max}}$ cannot be approximated with a bounded approximation ratio because the optimal schedule may have no lateness at all and any approximation leads to an unbounded approximation ratio. However, a variant of this problem can be easily approximated. This is known as the delivery-time model of the problem $1|r_j|L_{\text{max}}$. In this model, each job $J_i$ has its release time $r_i$, processing time $p_i$, and delivery time $d_i \geq 0$. After a job finishes its execution on a machine, its result (final product) needs $d_i$ amount of time to be delivered to the customer. The objective is to minimize the makespan $K$. Therefore, the effective deadline $d_i$ of job $J_i$ on the given single machine is $d_i = K - d_i$. Since $K$ is a constant, this is effectively equivalent to the case when $d_i$ is set to $-q_i$.

The delivery-time model of the problem $1|r_j|L_{\text{max}}$ can then be effectively approximated. Moreover, our problem to construct a good dependency graph for $T$ is indeed equivalent to the delivery-time model of the problem $1|r_j|L_{\text{max}}$. To show such equivalence, Algorithm 1 presents the detailed transformation. For each semaphore $\sigma_k$, suppose that $T_k$ is the set of tasks that use $\sigma_k$ (Line 1 in Algorithm 1). For each task set $T_k$, we transform the problem to construct $G_k$ to an equivalent delivery-time model of the problem $1|r_j|L_{\text{max}}$ (Line 3 to Line 8). Then, we construct the graph $G_k$ based on the derived schedule of an approximation algorithm for the delivery-time model of the problem $1|r_j|L_{\text{max}}$.

Theorem 7: An $\alpha$-approximation algorithm for the delivery-time model of the problem $1|r_j|L_{\text{max}}$ applied in Algorithm 1 guarantees to derive a dependency graph $G$ with $\text{len}(G) \leq \alpha \times \text{len}(G^*)$.

Proof: This theorem can be proved by a counterpart of the proof of Theorem 2. We will show that Algorithm 1 is in fact an L-reduction (i.e., a reduction that preserves the approximation ratio) from the input task set to the delivery-time model of the problem $1|r_j|L_{\text{max}}$. In this L-reduction, there is no loss of the approximation ratio.

First, by definition, two tasks are independent if they do not share any semaphore. Moreover, since the $TS-OCS$ problem assumes that a task accesses at most one binary semaphore, a task $r_i$ can only appear at most in one $T_k$ for a certain $k$. Therefore, $\text{len}(G^*) = \max_{k=1,2,\ldots,z} \text{len}(G_k)$.

To show that the reduction preserves the approximation ratio, we only need to prove the one-to-one mapping. One possibility is to prove that a schedule for the input instance of the problem $1|r_j|L_{\text{max}}$ delivers the last result at time $X$ if and only if the corresponding graph $G_k$ constructed by using Lines 9 and 10 in Algorithm 1 has a critical path length $X$. This is unfortunately not possible because a (technically bad but possible) schedule for the input instance of the problem $1|r_j|L_{\text{max}}$ can be arbitrarily altered by inserting useless delays.

Fortunately, for a given permutation to order the $X$ tasks in $T_k$, we can always construct a schedule for the input instance of the problem $1|r_j|L_{\text{max}}$ by respecting the given order and their release times. Such a schedule for the input instance of the problem $1|r_j|L_{\text{max}}$ delivers the last result at time $X$ if and only if the corresponding graph $G_k$ constructed by using Lines 9 and 10 in Algorithm 1 has a critical path length $X$. Moreover, the schedule for one such permutation is optimal for the input instance of the problem $1|r_j|L_{\text{max}}$.

Therefore, the approximation ratio is preserved while constructing $G_k$. According to the above discussions, $\text{len}(G_k) \leq \alpha \times \text{len}(G^*)$. Moreover,

$$\text{len}(G) \leq \max_{k=1,2,\ldots,z} \text{len}(G_k) \leq \alpha \times \max_{k=1,2,\ldots,z} \text{len}(G_k) = \alpha \times \text{len}(G^*)$$

According to Theorem 7 and Algorithm 1, we can simply apply the existing algorithms of the scheduling problem $1|r_j|L_{\text{max}}$ in the delivery-time model to derive $G^*$ by using well-studied branch-and-bound methods, see for example [13, 32, 35], or good approximations of $G^*$, see for example [22, 37]. Here, we will summarize several polynomial-time approximation algorithms. The details can be found in [22].

For the delivery-time model of the scheduling problem $1|r_j|L_{\text{max}}$, the extended Jackson's rule (JKS) is as follows: “Whenever the machine is free and one or more jobs is available for processing, schedule an available job with largest delivery time,” as explained in [22].

Lemma 2: The extended Jackson’s rule (JKS) is a polynomial-time 2-approximation algorithm for the dependency-graph construction problem.

Proof: This is based on Theorem 7 and the approximation ratio of JKS for the problem $1|r_j|L_{\text{max}}$, where the proof can...
Potts [37] observed some nice properties when the extended Jackson’s rule is applied. Suppose that the last delivery is due to a job \( J_i \). Let \( J_a \) be the earliest scheduled job so that the machine in the problem \( 1\mid r_j \mid L_{\text{max}} \) is idle between the processing of \( J_a \) and \( J_i \). The sequence of the jobs that are executed sequentially from \( J_a \) to \( J_i \) is called a critical sequence. By the definition of \( J_a \), all jobs in the critical sequence must be released no earlier than the release time \( r_a \) of job \( J_a \). If the delivery time of any job in the critical sequence is not shorter than the delivery time \( q_c \) of \( J_c \), then it can be proved that the extended Jackson’s rule is optimal for the problem \( 1\mid r_j \mid L_{\text{max}} \). However, if the delivery time \( q_b \) of a job \( J_b \) in the critical sequence is shorter than the delivery time \( q_c \) of \( J_c \), the extended Jackson’s rule may start a non-preemptive job \( J_b \) too early. Such a job \( J_b \) that appears last in the critical sequence is called the interference job of the critical sequence.

Potts [37] suggested to attempt at improving the schedule by forcing some interference job to be executed after the critical job \( J_c \). This is done by delaying the release time of \( J_b \) from \( r_b \) to \( r'_b = r_b + q_c \). This procedure is repeated for at most \( n \) iterations and the best schedule among the iterations is returned as the solution.

Lemma 3: Potts’ iterative process (Potts) is a polynomial-time 1.5-approximation algorithm for the dependency-graph construction problem.

Proof: This is based on Theorem 7 and the approximation ratio of Potts for the problem \( 1\mid r_j \mid L_{\text{max}} \), where the proof can be found in [22].

Hall and Shmoys [22] further improved the approximation ratio to 4/3 by handling a special case when there are two jobs \( J_b \) and \( J_i \) with \( p_l > P/3 \) and \( p_h > P/3 \) where \( P \) is the sum of \( p_j \) and running Potts’ algorithm for 2n iterations.

Lemma 4: Algorithm HS is a polynomial-time 4/3-approximation algorithm for the dependency-graph construction problem.

Algorithm 1 Graph Construction Algorithm

Input: set \( T \) of \( N \) tasks with \( z \) shared binary semaphores;

1. \( T_k \leftarrow \{ r_k \mid \sigma(r_k) = s_k \} \) for \( k = 1, 2, \ldots, z \);
2. \( J \leftarrow \emptyset \);
3. for each \( k = 1 \) to \( z \) do
4.    \( J_k \leftarrow \emptyset \);
5.   for each \( r_k \in T_k \) do
6.     create a job \( J_i \) with \( r_i \leftarrow C_{i,1}, p_i \leftarrow A_{i,1}, \) and \( q_i \leftarrow C_{i,2} \),
7.     where \( q_i \) is the delivery time;
8.   \( J \leftarrow J \cup \{ J_i \} \);
9. end for
10. apply an approximation algorithm to derive a non-preemptive schedule \( \rho_b \) for the delivery-time model of the problem \( 1\mid r_j \mid L_{\text{max}} \) on one machine;
11. construct the initial dependency graph \( G_k \) for \( T_k \), in which the following directed edges \((C_{i,1},A_{i,1})\) and \((A_{i,1},C_{i,2})\) for every task \( r_k \in T_k \) are created;
12. create a directed edge from \( A_{i,1} \) to \( A_{j,1} \) in \( G_k \) if job \( J_j \) is executed right after (but not necessarily consecutively) job \( J_i \) in the schedule \( \rho_b \);
13. end for
14. return \( G = G_1 \cup G_2 \cup \ldots \cup G_z \);

Proof: This is based on Theorem 7 and the approximation ratio of HS for the problem \( 1\mid r_j \mid L_{\text{max}} \), where the proof can be found in [22].

The algorithm that has the best approximation ratio for the delivery-time model of the problem \( 1\mid r_j \mid L_{\text{max}} \) is a polynomial-time approximation scheme (PTAS) developed by Hall and Shmoys [22].

Lemma 5: The dependency-graph construction problem admits a polynomial-time approximation scheme (PTAS), i.e., the approximation bound is \( 1 + \epsilon \) under the assumption that \( \frac{1}{\epsilon} \) is a constant for any \( \epsilon > 0 \).

6 Algorithms to Schedule Dependency Graphs

This section presents our heuristic algorithms to schedule the dependency graph \( G \) derived from Algorithm 1. We first consider the special case when there is a sufficient number of processors, i.e., \( M \geq N \).

Lemma 6: For a task set \( T \), to be scheduled on \( M \) identical processors, the makespan of the schedule which executes task \( r_k \) on only one processor \( i \) as early as possible by respecting to the precedence constraints defined in a given task dependency graph \( G \) is \( len(G) \) if \( M \geq N \). By definition, the schedule is a partitioned schedule for the given jobs and non-preemptive with respect to the jobs.

Proof: Since \( M \geq N \), all the tasks can start their first non-critical sections at time 0. Therefore, the critical section of task \( r_k \) arrives exactly at time \( C_{i,1} \). Then, the finishing time of the critical section of task \( r_k \) is exactly the longest path in \( G \) that finishes at the vertex representing \( A_{i,1} \). Therefore, the makespan of such a schedule is exactly \( len(G) \).

For the remaining part of this section, we will focus on the other case when \( M < N \). We will heavily utilize the concept of list schedules developed by Graham [21] and the extensions to schedule the dependency graph \( G \) derived from Section 5. A list schedule works as follows: Whenever a processor idles and there are subjobs eligible to be executed (i.e., all of their predecessors in \( G \) have finished), one of the eligible subjobs is executed on the processor. When the number of eligible subjobs is larger than the number of idle processors, many heuristic strategies exist to decide which subjobs should be executed with higher priorities. Graham [21] showed that the list schedules can be generated in polynomial time and have a \( 2 - \frac{1}{M} \) approximation ratio for the scheduling problem \( P\mid \text{prec}\mid C_{\text{max}} \).

For the rest of this section, we will explain how to use or extend list schedules to generate partitioned or semi-partitioned and preemptive or non-preemptive schedules based on \( G \).

6.1 Semi-Partitioned Scheduling

In a list schedule, since the subjobs of a task are scheduled individually, a task in the generated list schedule may migrate among different processors, thus representing a semi-partitioned schedule. However, a subjob by default is non-preemptive in list schedules.

The following lemma is widely used in the literature for the list schedules developed by Graham [21]. All the existing results of federated scheduling, e.g., [6], [15], [31].
for scheduling sporadic dependent tasks (that are not due to
synchronizations) all implicitly or explicitly use the property
in this lemma.

**Lemma 7**: The makespan of a list schedule of a given task
dependency graph \( G \) for task set \( T \) on \( M \) processors is at most
\[
\sum_{\tau_i \in T} (C_{i,1} + C_{i,2} + A_{i,1}) - \text{len}(G) + \text{len}(G).
\]

**Proof**: The original proof can be traced back to Theorem
1 by Graham \([21]\) in 1969. We omit the proof here as this
is a standard procedure in the proof of list schedules for the
scheduling problem \( P^{\mid \text{prec}} \mid C_{\max} \).

**Lemma 8**: If \( \text{len}(G) \leq \alpha \times \text{len}(G^*) \) for a certain \( \alpha \geq 1 \),
the makespan of a list schedule of the task dependency graph
\( G \) for task set \( T \) on \( M \) processors has an approximation bound
of \( 1 + \alpha - \frac{\alpha}{M} \) if \( M < N \).

**Proof**: Since \( M < N \), the makespan of a list schedule of
\( G \), denoted as \( L(\text{List}(G)) \), is
\[
L(\text{List}(G)) \leq \frac{\sum_{\tau_i \in T} C_{i,1} + C_{i,2} + A_{i,1}}{M} - \text{len}(G) + \text{len}(G)
\]
\[
= \frac{\sum_{\tau_i \in T} C_{i,1} + C_{i,2} + A_{i,1}}{M} + \text{len}(G)(1 - \frac{1}{M})
\]
assumption \[
\leq \frac{\sum_{\tau_i \in T} C_{i,1} + C_{i,2} + A_{i,1}}{M} + \alpha \times \text{len}(G^*)(1 - \frac{1}{M})
\]
Theorem \( 1 \)
\[
(1 + \alpha - \frac{\alpha}{M})\text{OPT}
\]

We now conclude the approximation ratio.

**Theorem 8**: When applying JKS (\( \alpha = 2 \), from Lemma \( 2 \)),
Potts (\( \alpha = 1.5 \), from Lemma \( 3 \)), HS (\( \alpha = 4/3 \), from
Lemma \( 4 \), and PTAS (\( \alpha = \epsilon \) for any \( \epsilon > 0 \), from Lemma \( 5 \)) to
generate the task dependency graph \( G \), the TS-OCS Makespan
problem admits polynomial-time algorithms to generate a
semi-partitioned schedule that has an approximation ratio of
\[
\begin{cases}
\alpha & \text{if } M \geq N \\
1 + \alpha - \frac{\alpha}{M} & \text{if } M < N
\end{cases}
\]

**Proof**: The case when \( M < N \) comes from Lemma \( 8 \)
The case when \( M \geq N \) comes from Lemma \( 6 \) and the fact
that a partitioned schedule is also a semi-partitioned schedule
by definition.

The default list schedulers are non-preemptive in the subjob
level. However, it may be more efficient if the second non-
critical section of a task can be preempted by a critical section.
Otherwise, the processors may be busy executing second non-
critical sections and a critical section has to wait. As a result,
not only this critical section itself but also its successors
in \( G \) may be unnecessary postponed and therefore increase
the makespan. This problem can be handled by preempting
second non-critical sections. Allowing such preemption in the
scheduler design can be achieved easily as follows:

- In the algorithm, the scheduling decision is made at a
time \( t \) when there is a subjob eligible or finished.
- Whenever a subjob representing a critical section is
eligible, it can be assigned to a processor that executes
a second non-critical section of a job by preempting that
subjob.

The makespan of the resulting schedule remains at most
\[
\frac{\sum_{\tau_i \in T} (C_{i,1} + A_{i,1} + C_{i,2}) - \text{len}(G)}{M} + \text{len}(G)
\] as in Lemma \( 7 \). Therefore, the approximation ratios in Theorem \( 8 \) still hold even if
preemption of the second non-critical sections is possible.

### 6.2 Partitioned Scheduling

In a partitioned schedule of the frame-based task set \( T \),
all subjobs of a task must be executed on the same processor.
Therefore, the list scheduling algorithm variant must ensure
that once the first subjob \( C_{i,1} \) of task \( \tau_i \) is executed on a
processor, all subsequent subjobs of task \( \tau_i \) are tied to the
same processor in any generated list schedule. Specifically,
the problem is termed as \( P^{\mid \text{prec}, \text{tied}} \mid C_{\max} \) in Section 2.3.

A special case of \( P^{\mid \text{prec}, \text{tied}} \mid C_{\max} \) has been recently studied
to analyze OpenMP systems by Sun et al. \([42]\) in
2017. They assumed that the synchronization subjob of a task
always takes place at the end of the task. Our dependency
graph \( G \) unfortunately does not satisfy the assumption because
the synchronization subjob is in fact in the middle of a task.
However, fixing this issue is not difficult. We illustrate the key
strategy by using Fig. 2. The subgraph \( \bar{G} \) of \( G \) that consists
of only the vertices of the first non-critical sections and the
critical sections in fact satisfies the assumption made by Sun et
al. \([42]\). Therefore, we can generate a multiprocessor schedule
for the dependency graph \( G \) on \( M \) processors by using the
BFS* algorithm (an extension of the breadth-first-scheduling
algorithm) by Sun et al. \([42]\). It can be imagined that the
subjobs that represent the second non-critical sections \( C_{i,2} \) are
background workload and can be executed only at the end of
the schedule or when the available idle time is sufficient to
complete \( C_{i,2} \).

Alternatively, in order to improve the parallelism, another
heuristic algorithm can be applied where all the first non-
critical sections are scheduled before any of the critical sections
using list scheduling. Once the first non-critical section
\( C_{i,1} \) of task \( \tau_i \) is assigned on a processor, the remaining
execution of task \( \tau_i \) is forced to be executed on that processor.

![Fig. 2. A schematic of a tied task dependency graph for a task set with one binary semaphore.](image)
processor. For completeness, we illustrate the algorithm in Algorithm 2 in the Appendix.

7 Timing Anomaly

So far, we assume that $C_{i,1}$, $A_{i,1}$, and $C_{i,2}$ are exact for a task $\tau_i$. However, the execution of a subjob of task $\tau_i$ can be finished earlier than the worst case. It should be noted that list schedules are in this case not sustainable, i.e., the reduction of the execution time of a subjob can lead to a worse makespan due to the well-known multiprocessor timing anomaly observed by Graham [21]. There are three ways to handle such timing anomaly: 1) ignore the early completion and stick to the offline schedule, 2) reclaim the unused time (slack) carefully without creating timing anomaly, e.g., [30], or 3) use a safe upper bound, e.g., Lemma 7 to account for all possible list schedules. Each of them has advantages and disadvantages. It is up to the designers to choose whether they want to be less effective (Option 1), pay more runtime overhead (Option 2), or be more pessimistic by taking always a safe upper bound (Option 3).

Due to multiprocessor timing anomaly, a dependency graph with a longer critical path may have a better makespan in the resulting list schedule. Our approach can be easily improved by returning and scheduling the intermediate dependency graphs in Algorithms Potts and HS.

8 Periodic Tasks with Different Periods

Our approach can be extended to periodic tasks with different periods under an assumption that a binary semaphore is only shared among the tasks that have the same period. For each of the $z$ semaphores, a DAG is constructed using Algorithm 1. Afterwards, the $z$ resulting DAGs can be scheduled using any approach for multiprocessor DAG scheduling, e.g., global scheduling [29], Federated Scheduling [31] as well as enhanced versions like Semi-Federated Scheduling [25] and Reservation-Based Federated Scheduling [43].

9 Evaluations

This section presents the evaluations of the proposed approach. We will first explain how our approach can be implemented by using existing routines in LITMUSRT and provide the measured overhead in LITMUSRT. Then, we will demonstrate the performance of the proposed approach by applying numerical evaluations for different configurations.

9.1 Implementations and Overheads

The hardware platform used in our experiments is a cache-coherent SMP, consisting of two 64-bit Intel Xeon Processor E5-2650Lv4 running at 1.7 GHz, with 35 MB cache and 64 GB of main memory. We have implemented our dependency graph approach in LITMUSRT, in order to investigate the overheads. Both partitioned and semi-partitioned scheduling algorithms presented in Section 6 have been implemented in LITMUSRT under the plug-in Partitioned Fixed Priority (P-FP), detailed in the Appendix. The patches of our implementation have been released in [41].

In Table 1 we report the following overheads of different protocols, including the existing protocols DPCP, and MPCP in LITMUSRT and our implementation of the partitioned dependency graph approach (PDGA) and the semi-partitioned dependency graph approach (SDGA):

- **CXS**: context-switch overhead.
- **RELEASE**: time spent to enqueue a newly released job in a ready queue.
- **SCHED2**: time spent to perform post context switch and management activities.
- **SCHED**: time spent to make a scheduling decision (scheduler to find the next job).
- **SEND-RESCHED**: inter-processor interrupt latency, including migrations.

Table 1 shows that the overheads of our approach and of other protocols implemented in LITMUSRT are comparable.

9.2 Numerical Performance Evaluations

We conducted evaluations with $M = 4, 8$ and 16 processors. Depending on $M$, we generate 1000 task sets, each with $10M$ tasks. For each task set $T$, we generated synthetic tasks with $\sum_{\tau_i \in T} C_{i,1} + C_{i,2} + A_{i,1} = M$ by applying the RandomFixedSum method [18] and enforced that $C_{i,1} + C_{i,2} + A_{i,1} \leq 0.5$ for each task $\tau_i$. The number of shared resources (binary semaphores) was set to $z \in \{4, 8, 16\}$. The length of the critical section $A_{i,1}$ is a fraction of the total execution time $C_{i,1} + C_{i,2} + A_{i,1}$ of task $\tau_i$, depended on $\beta \in \{5\% - 50\%\}$. The remaining part $C_i$ was split into $C_{i,1}$ and $C_{i,2}$ by drawing $C_{i,1}$ randomly uniform from $[0, C_i]$ and setting $C_{i,2}$ to $C_i - C_{i,1}$.

For a generated task set $T$, we calculated a lower bound $LB$ on the optimal makespan based on Eq. (1). Since deriving $len(G^*)$ is computationally expensive, we used $\min_{\tau_i \in T} C_{i,1} + \min_{\tau_j \in T} C_{j,2} + \max_{k = 1, \ldots, z} C_{k,1}^\text{CriticalSum}$ as a safe approximation for $len(G^*)$, where $C_{k,1}^\text{CriticalSum}$ is the sum of the lengths of the critical sections that share semaphore $s_k$. If the relative deadline of the task set is less than $LB$, the task set is not schedulable by any algorithm. We compare the performance of different algorithms according to the acceptance ratio by setting the relative deadline $D = T$ in the range of $[LB, 1.5LB]$. We name the developed algorithms using the following rules: 1) JKS/POTTS: in the first part; using the extended Jackson’s rule or Potts to construct the dependency graph; 2) SPP/P in the second part: semi-partitioned or partitioned scheduling algorithm is applied; 3) P/NP in the third part: preemptive or non-preemptive for the second non-critical sections.

We evaluated all 8 combinations under different settings as shown in Fig. 3. Due to space limitation, only a subset of the
In general, the semi-partitioned scheduling algorithms clearly outperform the partitioned strategies, independently from the algorithm used to construct the dependency graph. In addition, the preemptive scheduling policy with respect to the second computation segment is superior to the non-preemptive strategy and POTTS (usually) performs slightly better than JKS. We analyze the effect of the three parameters individually by changing:

1) \( M = z \in \{8, 16\} \) (Fig. 3(a) and Fig. 3(b)): increasing \( z \) and \( M \) also slightly increases the difference between the semi-partitioned and the partitioned approaches.

2) \( z \) for a fixed \( M \), i.e., \( z \in \{4, 8, 16\} \) and \( M = 8 \) (Fig. 3(c), Fig. 3(a), and Fig. 3(d)): when the number of resources is decreased compared to the number of processors, the performance gap between preemptive and non-preemptive scheduling increases.

3) Workload of Shared Resources, i.e., \( \beta \in \{5\% - 10\%, 10\% - 40\%, 40\% - 50\%\} \) (Fig. 3(e), Fig. 3(a), and Fig. 3(f)): if the workload of the critical sections is increased, the difference between preemptive and non-preemptive scheduling approaches is more significant.

We also compare our approach with the Resource Oriented Partitioned (ROP) scheduling with release enforcement by von der Brüggen et al. [44] which is designed to schedule periodic tasks with one critical section on a multiprocessor platform. The concept of the ROP is to have a resource centric view instead of a processor centric view. The algorithm 1) binds the critical sections of the same resource to the same processor, thus enabling well known uniprocessor protocols like PCP to handle the synchronization, and 2) schedule the non-critical sections on the remaining processors using a state-of-the-art scheduler for segmented self-suspension tasks, namely SEIFDA [45]. Among the methods in [44], we evaluated FP-EIM-PCP (under fixed-priority scheduling) and EDF-EIM-PCP (under dynamic-priority scheduling). It has been shown in [44] that EDF-EIM-PCP dominates all existing methods. We perform another set of evaluations by adopting aforementioned settings and testing the utilization level in a step of 5\%, where the utilization of a task set \( T \) is \( \sum_{i \in T} C_{t_{i} + \tau} \), \( \tau \). Fig. 4 presents the evaluation results. Due to space limitation, only a subset of the results is presented, but the others have very similar curve tendencies. For readability, we only select two combinations in our proposed approach that outperform the others. The results in Fig. 4 show that for frame-based tasks, our approach outperforms ROP significantly. We note that Fig. 4 is only for frame-based tasks, and the results for periodic task systems discussed in Section 8 are further presented in Appendix.

10 Conclusion

This paper tries to answer a few fundamental questions when real-time tasks share resources in multiprocessor systems. Here is a short summary of our findings:

- The fundamental difficulty is mainly due to the sequencing of the mutual exclusive accesses to the share resources (binary semaphores). Adding more processors, removing periodicity and job recurrence, introducing task migration, or allowing preemption does not make the problem easier from the computational complexity perspective.

- The performance gap of partitioned and semi-partitioned scheduling in our study is mainly due to the capability to schedule the subjobs constrained by the dependency graph. Although partitioned scheduling may seem much worse than semi-partitioned scheduling in our evaluations, this is mainly due to the lack of understanding of the problem \( P|\text{prec, tied}|C_{\text{max}} \) in the literature. Further explorations are needed to understand these scheduling paradigms for a given dependency graph.

- The dependency graph approach is not work-conserving for the critical sections, since a critical section may be ready but not executed due to the artificially introduced precedence constraints. Existing multiprocessor synchronization protocols mainly assume work-conserving for granting the accesses of the critical sections via priority boosting. Our study reveals a potential to consider cautious and non-work-conserving synchronization protocols in the future.
**Appendix**

**Proof of Theorem 6** Due to the design of the task set, there are only \(N\) different dependency graphs, depending on the position of \(\tau_1\) in the execution order. Suppose that the critical section of task \(\tau_1\) is the \(j\)-th critical section in the dependency graph. It can be proved that the critical path of this dependency graph is \(j\delta + Q + N\delta\). We sketch the proof:

- The non-critical section \(C_{1,2}\) must be part of the critical path since \(C_{1,2} = \frac{Q}{M} + N\delta\), which is greater than any \((N - 1)A_{i,1} + C_{i,2}\) for any \(i = 2, 3, \ldots, N - 1\).
- The longest path that ends at the vertex representing \(A_{1,1}\) has 1) one non-critical section, 2) \(j - 1\) critical sections from \(\tau_i\) for \(i = 2, 3, \ldots, N\), and 3) 1 critical section from task \(\tau_1\). Therefore, this length is \(j\delta + Q + \frac{N\delta}{M} = j\delta + Q - \frac{Q}{M}\).
- Combining the two scenarios, we reach the conclusion.

Therefore, the dependency graph \(G^*\) that has the minimum critical path length is the one where \(\tau_1\)'s critical section is the first one among the \(N\) critical sections. The optimal schedule of the dependency graph \(G^*\) on \(M\) processors has the following properties:

- Task \(\tau_1\) finishes its critical section at time \(\delta + Q - \frac{Q}{M}\).
- Before time \(\delta + Q - \frac{Q}{M}\), none of the second non-critical sections is executed. Therefore, the makespan of any feasible schedule \(S(G^*)\) of \(G^*\) on \(M\) processors is

\[
L(S(G^*)) \geq \delta + Q - \frac{Q}{M} + \frac{N\delta}{M} = \delta + Q - \frac{Q}{M} + \left(\frac{M^2 - M + 1}{M}\right)\frac{Q}{M} + N\delta
\]

Moreover, when the scheduling policy is either semi-partitioned or partitioned scheduling, by the pigeon hole principle, at least one processor must execute \(\left\lfloor \frac{N}{M} \right\rfloor\) of the \(N\) second non-critical sections no earlier than \(\delta + Q - \frac{Q}{M}\). Therefore, the makespan of a feasible semi-partitioned or partitioned schedule \(S_p\) of \(G^*\) on \(M\) processors is

\[
L(S_p(G^*)) \geq \delta + Q - \frac{Q}{M} + \left\lfloor \frac{N}{M} \right\rfloor \frac{Q}{M} = \delta + Q - \frac{Q}{M} + M - 1 + \frac{Q}{M}
\]

We can have another feasible partitioned schedule \(S^*\):

- The first non-critical section \(\tau_1\) is executed on processor \(M\), and the first non-critical sections of the other \(N - 1\) tasks are executed on the first \(M - 1\) processors based on list scheduling. All the first non-critical sections finish no later than \(M\delta\). Each of the first \(M - 1\) processors executes exactly \(M\) tasks with identical properties on these \(M - 1\) processors.
- The critical sections of tasks \(\tau_{N-1}, \tau_{N-2}, \ldots, \tau_1\) are executed sequentially by following the above reversed-index order on the same processor of the corresponding first non-critical sections, starting from time \(M\delta\).
- At time \(M\delta + N\delta\), all the second non-critical sections of \(\tau_2, \ldots, \tau_N\) are eligible to be executed. We execute them in parallel on the first \(M - 1\) processors by respecting the partitioned scheduling strategy. That is, each of the first \(M - 1\) processors executes exactly \(M\) tasks with \(C_{1,2} = Q/M\). The makespan of these \(N - 1\) tasks is \((N + M)\delta + \frac{(N - 1)\delta}{M - 1} = (N + M)\delta + Q\).
- At time \(M\delta + N\delta\), the critical section of \(\tau_1\) starts its execution on processor \(M\). Furthermore, at time \((N + M)\delta + Q - \frac{Q}{M}\), the second non-critical section of \(\tau_1\) is executed on processor \(M\) and it is finished at time \((N + M)\delta + Q + N\delta = (2N + M)\delta + Q\).

As a result, the makespan of the above partitioned schedule \(S^*\) is exactly \((2N + M)\delta + Q\).

Therefore, the approximation bound of the optimal task dependency graph approach is at least \(\frac{L(S(G^*))}{L(S^*)}\) under any scheduling paradigm and is at least \(\frac{L(S(G^*))}{L(S^*)}\) under partitioned or semi-partitioned scheduling paradigm. We reach the conclusion by taking \(\delta \rightarrow 0\).

**Pseudo-code of the Partitioned Preemptive Scheduling in Section 6.2** For notational brevity, we define two vertices \(v_{i,1}\) and \(v_{i,2}\) to represent the first and second non-critical sections of task \(\tau_i\) and \(v_{i,2}\) to represent the critical section of task \(\tau_i\). Let \(T_m\) be the set of tasks in \(T\) assigned to processor \(m\) for \(m = 1, 2, \ldots, M\). The pseudo-code is listed in Algorithm 7. It consists of three blocks: initialization from Line 1 to Line 4, scheduling of the first non-critical sections and the critical sections of the tasks according to \(G\) from Line 5 to Line 23, and scheduling of the second non-critical sections of the tasks from Line 24 to Line 28.

The first block is self-explained in Algorithm 2. We will focus on the second and third blocks of Algorithm 7. Our scheduling algorithm executes the first non-critical sections and the critical sections non-preemptively. Whenever a subjob finishes at time \(t\), we examine the following scenarios on each processor \(m\) for \(m = 1, 2, \ldots, M\):

- If there is a pending critical section on processor \(m\) that is eligible at time \(t\) according to the dependency graph \(G\), we would like to execute the critical section as soon as possible. Therefore, this critical section is executed as soon as it is eligible and the processor idles (i.e., Lines 12-13).
- Else if there is a task in \(T_m\) in which its first non-critical section has not finished yet at time \(t\), we would like to execute it (Lines 14-15).
- Otherwise, there is no eligible subjob to be executed at time \(t\). If there is still an unassigned task, we select one
Algorithm 2 Tied List-Scheduling (Partitioned Preemptive)

Input: \( G, T, M \) with \( |T| > M \);

1: \( \text{current} \leftarrow 0; \)
2: assign one task \( \tau_i \) in \( T \) to task set \( T_m \) to be executed on processor \( m \);
3: \( T \leftarrow T \setminus \bigcup_{m=1}^{M} T_m; \)
4: execute \( v_{i,1} \) of the unique task \( \tau_i \) in \( T_m \) on processor \( m \) from time 0, i.e., \( \rho(t,m) \leftarrow \tau_i \) for \( t \in [0,C_{i,1}) \), for each \( m = 1,2,\ldots,M \);
5: while \( \exists \tau_i \) such that \( v_{i,2} \) has not finished yet at time \text{current} do
6: let \( t \) be the minimum time instant greater than \text{current} such that the schedule finishes a subjob at time \( t \);
7: \( \text{current} \leftarrow t; \)
8: for \( m = 1,2,\ldots,M \) do
9: if processor \( m \) is busy executing a subjob at time \( t \) then continue;
10: else if processor \( m \) idles (or just finishes a subjob) at time \( t \) then
11: if \( \exists \tau_i \in T_m \), in which \( v_{i,2} \) has not finished yet and \( v_{i,1} \) is eligible according to \( G \) at time \( t \) then
12: execute \( \tau_i \)’s critical section from time \( t \) to \( t + A_{i,1} \) non-preemptively on processor \( m \), i.e., \( \rho(t,m) \leftarrow \tau_i \) for \( t \in [t,t+A_{i,1}) \);
13: else if \( \exists \tau_i \in T_m \), in which \( v_{i,1} \) has not finished yet at \( t \) then
14: execute \( v_{i,1} \) from time \( t \) on \( t + C_{i,1} \) processor \( m \), i.e., \( \rho(t,m) \leftarrow \tau_i \) for \( t \in [t,t+C_{i,1}) \);
15: else if \( \exists \tau_i \in T_m \), in which \( v_{i,1} \) has not finished yet at \( t \) then
16: execute \( v_{i,1} \) from time \( t \) on \( t + C_{i,1} \) processor \( m \), i.e., \( \rho(t,m) \leftarrow \tau_i \) for \( t \in [t,t+C_{i,1}) \);
17: else if \( T \) is not empty then
18: select a task \( \tau_i \) and remove \( \tau_i \) from \( T \), i.e., \( T \leftarrow T \setminus \{ \tau_i \}; \)
19: assign task \( \tau_i \) to processor \( m \), i.e., \( T_m \leftarrow T_m \cup \{ \tau_i \}; \)
20: execute \( v_{i,1} \) from time \( t \) to \( t + C_{i,1} \) processor \( m \), i.e., \( \rho(t,m) \leftarrow \tau_i \) for \( t \in [t,t+C_{i,1}) \);
21: end if
22: end if
23: end while
24: for \( m = 1,2,\ldots,M \) do
25: for each task \( \tau_i \) in \( T_m \) do
26: schedule the second non-critical section \( v_{i,3} \) of task \( \tau_i \) as background workload with the lowest priority preemptively as early as possible but no earlier than the finishing time of its critical section;
27: end for
28: end for

and assign it to processor \( m \) by starting its first non-critical section at time \( t \) (Lines 16-19).

In all the above steps, task \( \tau_i \) can be arbitrarily selected if there are multiple tasks satisfying the specified conditions. We note that the schedule is in fact offline. Therefore, after we finish the schedule of the first non-critical sections and the critical sections, in the third block in Algorithm 2 we can pad the idle time of the schedule on a processor \( m \) with the second non-critical sections assigned on processor \( m \), starting from time 0. The only attention is not to start earlier than the finishing time of its critical section. Of course, to minimize the makespan, we should always pad the idle time as early as possible.

Implementation in LITMUS\textsuperscript{RT} To force the tasks to follow the pre-defined order to execute the critical sections, we added several elements into the \( rt\_params \) structure which is used to define the property for each task, i.e., priority, period, execution time, etc. Two parameters are added: 1) \( rt\_order \) to define the order of the task to execute the critical section, and 2) \( rt\_total \) to define the number of the tasks that shared the same resource. To implement the binary semaphores under the dependency graph approach, we created two new structures, \( pdga\_semaphore \) for the partitioned dependency graph approach (PDGA), and \( sdga\_semaphore \) for the semi-partitioned dependency graph approach (SDGA). In these structures, one parameter is defined to control the order of the execution named \( current\_serving\_ticket \). When a task requests the resource, it will compare its \( rt\_order \) with the semaphore’s \( current\_serving\_ticket \), if they are equal, the task will be granted to access the resource and start its critical section; if not, the task will be added to the wait-queue, which is sorted by the tasks’ parameter \( rt\_order \). Once a task has finished its critical section, it will increase the semaphore’s \( current\_serving\_ticket \) by 1, and check the head of the wait-queue do the comparison again. Once the \( current\_serving\_ticket \) reaches to the \( rt\_total \), which means one dependency graph has finished its execution of the critical sections, then the parameter \( current\_serving\_ticket \) will be reset to 0 to start the next iteration. The only difference between PDGA and SDGA is that we added the migration function for SDGA to support the semi-partitioned algorithm.

Evaluations for Periodic Task Sets We also performed evaluations for periodic task systems, when a binary semaphore is only shared by the tasks with the same period described in Section 8. We used similar configurations as in Section 9.2 to generate the task sets. For the tasks that share the same semaphore, they have the same period in the range of \([1,10]\). The following algorithms were evaluated:

- LP-GFP-FMLP [7]: a linear-programming-based (LP) analysis for global FP scheduling using the FMLP [7].
- LP-PFP-DPCP [9]: LP-based analysis for partitioned FP and DPCP [39]. Tasks are assigned using Worst-Fit-Decreasing (WFD) as proposed in [9].
- LP-PFP-MPCP [9]: LP-based analysis for partitioned FP using MPCP [38]. Tasks are partitioned according to WFD as proposed in [9].
- GS-MSRP [43]: the Greedy Slacker (GS) partitioning heuristic with the spin-based locking protocol MSRP [20] under Audsley’s Optimal Priority Assignment [4].
- LP-GFP-PIP: LP-based global FP scheduling using the Priority Inheritance Protocol (PIP) [17].
- FP-EIM-PCP [44]: The ROP scheduling under fixed-priority scheduling and release enforcement.
- EDF-EIM-PCP [44]: The ROP scheduling under dynamic-priority scheduling and release enforcement.
- PottsSF: Our approach by applying algorithm Potts for generating \( G \) and semi-federated scheduling in [25].
- JKS-SF: Our approach by applying algorithm JKS for generating \( G \) and semi-federated scheduling in [25].

For one evaluation point, 100 synthetic task sets were generated and tested. Only a subset of the results is presented in Fig. 5 due to space limitation, and LP-PFP-MPCP is not presented for better readability since it performs the worst for the evaluations in Fig. 5. The figure clearly shows that POTTTS-SF and JKS-SF significantly outperform the other approaches.
