ABSTRACT

The time evolution of the probability density function (PDF) of the mass density is formulated and solved for systems in free-fall using a simple approximate function for the collapse of a sphere. We demonstrate that a pressure-free collapse results in a power-law tail on the high-density side of the PDF. The slope quickly asymptotes to the functional form \( P_V(\rho) \propto \rho^{-1.54} \) for the (volume-weighted) PDF and \( P_M(\rho) \propto \rho^{-0.54} \) for the corresponding mass-weighted distribution. From the simple approximation of the PDF we derive analytic descriptions for mass accretion, finding that dynamically quiet systems with narrow density PDFs lead to retarded star formation and low star formation rates (SFRs). Conversely, strong turbulent motions that broaden the PDF accelerate the collapse causing a bursting mode of star formation. Finally, we compare our theoretical work with observations. The measured SFRs are consistent with our model during the early phases of the collapse. Comparison of observed column density PDFs with those derived from our model suggests that observed star-forming cores are roughly in free-fall.

Key words: galaxies: star formation – gravitation – ISM: clouds

1. INTRODUCTION

The density probability density function (PDF) is a powerful tool for analyzing astrophysical systems; in both non-gravitating and strongly self-gravitating systems, it reveals key aspects of the underlying physical processes. For supersonic non-gravitating turbulent gas in an isothermal environment the density PDF is log-normal (Vázquez-Semadeni 1994; Padoan et al. 1997; Passot & Vázquez-Semadeni 1998; Klessen 2000; Kritsuk et al. 2007; Lemaster & Stone 2008; Federrath et al. 2008, 2010; Price & Federrath 2010; Konstandin et al. 2012a). When self-gravity becomes important, the probability of finding dense regions increases and a power-law tail develops on the high-density side of the PDF (Klessen 2000; Slyz et al. 2005; Vázquez-Semadeni et al. 2008; Cho & Kim 2011; Kritsuk et al. 2011; Collins et al. 2012). Recent observations of column-density PDFs support these theoretical predictions (Kainulainen et al. 2009; Froebrich & Rowles 2010; Lombardi et al. 2010; Schneider et al. 2012).

The density PDF can be used to evaluate key aspects of star formation, like the efficiency and the stellar initial mass function (IMF; see, e.g., Krumholz et al. 2005; Padoan et al. 1997; Hennebelle & Chabrier 2008; Shadmehri & Elmegreen 2011; Veltchev et al. 2011; Donkov et al. 2011, 2012).

A possible theoretical relation between the log-normal character of the density PDF in turbulent media and the appearance of a power-law tail at high densities has been developed by Elmegreen (2011), using convolution PDFs that depend on the ratio of maximum to minimum average cloud density, i.e., the core-to-edge average density ratio.

In this paper we develop a model for the evolution of the density PDF, based on free-fall collapse. We start with the initial density PDF of a gaseous system, not specifying its spatial structure, nor how it evolved to this state. We then evolve the system in time with two approximations. In the first one we apply the free-fall analysis directly to the density PDF. In the second approach we assume that the system can be described by an ensemble of free-falling homogeneous spheres, such that the subsequent time evolution is solely determined by the collapse of the individual spheres.

Using the time evolution of the PDF, we derive the free-fall accretion rate, defined as the rate at which gas evolves above an arbitrary threshold density. This accretion rate can then be tuned to serve as an estimate for the star formation rate (SFR).

The model is compared to observations of star-forming regions taken from Kainulainen et al. (2009), Heiderman et al. (2010) and Schneider et al. (2012). The observed SFR is consistent with the values of the free-fall model at early stages of the collapse. Comparing the observed column density PDFs with our model suggests that the star-forming cores are in free-fall.

2. ANALYTIC COLLAPSE MODEL

We begin with a review of the analytic solution for a uniform-density sphere in free-fall. The time evolution of the density can then be described by a simple approximate function and applied to the density PDF. The radius, \( r \), of such a sphere obeys

\[
\frac{d^2 r}{dt^2} = -\frac{GM}{r^2} = -\frac{4\pi G \rho_0 r^3}{3r^2}.
\]

Here, \( G \) is Newton’s constant, \( M \) is the mass of the sphere, \( \rho_0 \) and \( r_0 \) denote the initial density and radius of the sphere at time \( t = 0 \), and the collapse starts from rest. Using the free-fall time,

\[
t_f = \sqrt{\frac{3\pi}{32G\rho_0}},
\]

In the sequel, we shall often refer to the power-law tail that develops on the high-density side of the PDF simply as “the tail,” and to its logarithmic slope simply as “the slope.”
Inverting Equation (5) yields
\[ \tau = \frac{1}{\tau} \] as the characteristic time, and defining the dimensionless radius \( \zeta = r/r_0 \), and the dimensionless time \( \tau_{\text{exact}} = t/t_{\text{ff}} \), one obtains the equation
\[ \frac{d^2 \zeta}{d \tau_{\text{exact}}^2} = -\frac{\pi^2}{8\zeta^2}. \] (3)
with initial conditions \( \zeta = 1 \) and \( d\zeta/d\tau_{\text{exact}} = 0 \) at \( \tau_{\text{exact}} = 0 \). This can be solved to give
\[ \tau_{\text{exact}} = \frac{2}{\pi} (\arccos \sqrt{\zeta} + \sqrt{(1 - \zeta)}) \] (4)
equation cannot be inverted analytically, but a good approximation for \( \zeta(\tau) \) can be obtained by setting
\[ \tau = \sqrt{1 - \zeta^{3/a}}. \] (5)
Equation (5) deviates least from the exact solution (Equation (4)) if we substitute \( a = 1.8614 \), and Figure 1 shows the error, \( 1 - \tau/\tau_{\text{exact}} \), that results from this and other substitutions. Inverting Equation (5) yields
\[ r(\tau) = r_0 (1 - \tau^2)^{a/3}. \] (6)
We note that free-fall proceeds very slowly at the beginning. After 50% of a freefall time the radius has decreased by only 16%, and after 99% of a freefall time the radius is only an order of magnitude smaller. Assuming the mass in the sphere, \( M = 4\pi/3\rho t^3 \), to be constant during the collapse, Equation (6) gives
\[ \rho(\tau) = \rho_0 (1 - \tau^2)^{-a}. \] (7)
With this equation, we can now explicitly compute the density as a function of time starting with an initial density \( \rho_0 \). We note that a sphere with initially uniform density maintains the uniform density distribution during the entire free-fall collapse. In addition, the time derivative of the density, which we need later, is given by
\[ \frac{d\rho}{dt} = \frac{12Q}{a} \rho_0^2 t (1 - Q_{\rho \text{df}})^{a-1}, \] (8)
where we introduce
\[ Q = \frac{32G}{3\pi} \] (9)
to simplify many of the equations.

Figure 1. Fractional difference between the approximate solution of Equation (5) and the exact solution of Equation (4).

as the characteristic time, and defining the dimensionless radius \( \zeta = r/r_0 \), and the dimensionless time \( \tau_{\text{exact}} = t/t_{\text{ff}} \), one obtains the equation
\[ \frac{d^2 \zeta}{d \tau_{\text{exact}}^2} = -\frac{\pi^2}{8\zeta^2}. \] (3)
with initial conditions \( \zeta = 1 \) and \( d\zeta/d\tau_{\text{exact}} = 0 \) at \( \tau_{\text{exact}} = 0 \). This can be solved to give
\[ \tau_{\text{exact}} = \frac{2}{\pi} (\arccos \sqrt{\zeta} + \sqrt{(1 - \zeta)}) \] (4)
equation cannot be inverted analytically, but a good approximation for \( \zeta(\tau) \) can be obtained by setting
\[ \tau = \sqrt{1 - \zeta^{3/a}}. \] (5)
Equation (5) deviates least from the exact solution (Equation (4)) if we substitute \( a = 1.8614 \), and Figure 1 shows the error, \( 1 - \tau/\tau_{\text{exact}} \), that results from this and other substitutions. Inverting Equation (5) yields
\[ r(\tau) = r_0 (1 - \tau^2)^{a/3}. \] (6)

With this equation, we can now explicitly compute the density as a function of time starting with an initial density \( \rho_0 \). We note that a sphere with initially uniform density maintains the uniform density distribution during the entire free-fall collapse. In addition, the time derivative of the density, which we need later, is given by
\[ \frac{d\rho}{dt} = \frac{12Q}{a} \rho_0^2 t (1 - Q_{\rho \text{df}})^{a-1}, \] (8)
where we introduce
\[ Q = \frac{32G}{3\pi} \] (9)
to simplify many of the equations.

Figure 2. Sketch of the time evolution of a density bin in the PDF. The conservation of probability translates into the conservation of fractional volume.

3. TIME EVOLUTION OF THE DENSITY PDF

3.1. Analytic Description

The density PDF gives a statistical description of the distribution of density in a system. In the previous section we described a single sphere with uniform density distribution, whose PDF is a Dirac \( \delta \) function, \( P(\rho', \tau) = \delta(\rho' - \rho(\tau)) \). In the following we therefore consider a large ensemble of uniform density spheres with different initial densities \( \rho_0(\tau = 0) \). We must distinguish between the (volume-weighted) density PDF and its corresponding mass-weighted distribution,

\[ P_V = \frac{1}{V_{\text{tot}}} \frac{dV}{d\rho}, \] (10)

\[ P_M = \frac{1}{M_{\text{tot}}} \frac{dM}{d\rho}. \] (11)
The distributions are normalized to the total volume, \( V_{\text{tot}} \), and the total mass, \( M_{\text{tot}} \), respectively, such that the integral over the PDF is unity, \( \int_0^\infty d\rho P = 1 \).

For free-fall from rest, the density is a monotonic function of time such that, if we consider two separately collapsing uniform spheres having initial densities \( \rho_1(0) \) and \( \rho_2(0) \) \( (> \rho_1(0)) \), then for all times \( t \) satisfying \( 0 < t < t_0(\rho_1(0)) \), \( \rho_1(t) > \rho_2(t) \), i.e., the evolutionary paths, \( \rho_1(t) \) and \( \rho_2(t) \) do not cross. We can use this mathematical property to derive an analytic description for the time evolution of the density PDF. For a (large) set of independently collapsing spheres with different initial densities we obtain an initial density PDF, for which we can use the discretization illustrated on Figure 2. Due to the conservation of probability density, the area of a bin on this plot stays constant over time, and so

\[ P_V(t_1) = P_V(t_0) \frac{\Delta \rho_0}{\Delta \rho_1}. \] (12)

Starting with an arbitrary but fixed \( \Delta \rho_0 \) at time \( t_0 \), the value for \( \Delta \rho_1 \) at time \( t_1 \) can be calculated from the analytic function for \( \rho(t) \), as demonstrated below.

We can transform \( P_V \) to \( P_M \) using

\[ \frac{dV}{d\rho} = \frac{dV}{dM} \frac{dM}{d\rho} = \frac{1}{\rho} \frac{dM}{d\rho}. \] (13)
Combining this with Equation (12), we obtain
\[ P_M(t_1) = P_M(t_0) \frac{\rho_1 \Delta \rho_0}{\rho_0 \Delta \rho_1}. \] (14)

The bin width \( \Delta \rho_1 \) can be written in terms of \( \Delta \rho_0, \rho_0, \) and \( t \), using Equation (7),
\[ \Delta \rho_1 = (\rho_0 + 0.5 \Delta \rho_0)(1 - Q(\rho_0 + 0.5 \Delta \rho_0)t^2) - (\rho_0 - 0.5 \Delta \rho_0)(1 - Q(\rho_0 - 0.5 \Delta \rho_0)t^2)^{-a}. \] (15)
In the limit as \( \Delta \rho_0 \to 0 \), we have
\[ q \equiv \lim_{\Delta \rho_0 \to 0} \left( \frac{\Delta \rho_0}{\Delta \rho_1} \right) = \frac{(1 - t^2)^{a+1}}{1 + t^2(a-1)}. \] (16)
where we have defined \( q \) for convenience in subsequent analyses.

### 3.2. Evolution of the High-density Part of the PDF

We now make use of the simple approximation for \( \rho(t) \) (Equation (5)), to derive the time evolution of the density PDF and, in particular, we focus on the high-density part. In this context, it is convenient to use logarithmic scaling. Specifically we need to determine
\[ \frac{d \ln P}{d \ln \rho} = \frac{d \ln P}{d \rho} \frac{d \rho}{d \ln \rho}, \] (17)
as a function of density, \( \rho \), and time, \( t \). The high-density slope of the PDF is then given by the limit as \( t \to 1 \). The second term on the right-hand side of Equation (17) is
\[ \frac{d \rho}{d \ln \rho} = \rho \left( 1 + \frac{a \tau^2}{1 - \tau^2} \right)^{-1}, \] (18)
and vanishes as \( \tau \to 1 \), because the second term in the brackets dominates. For the first term on the right-hand side of Equation (17) we need to distinguish between \( P_V \) and \( P_M \).

Using Equations (12) and (14) the derivative for the first case takes the form
\[ \frac{d \ln P_V(t_1)}{d \rho_0} = \frac{d \ln P_V(t_0)}{d \rho_0} + \frac{d \ln q}{d \rho_0}, \] (19)
and for the latter one it takes the form
\[ \frac{d \ln P_M(t_1)}{d \rho_0} = \frac{d \ln P_M(t_0)}{d \rho_0} + \frac{d \ln q}{d \rho_0} + \frac{d \ln \rho/\rho_0}{d \rho_0}. \] (20)

The term containing \( q \) in Equations (19) and (20) reads
\[ \frac{d \ln q}{d \rho_0} = -\frac{\tau^2}{\rho_0} \left( \frac{a+1}{1 - \tau^2} + \frac{a-1}{1 + \tau^2(a-1)} \right). \] (21)
and diverges as \( \tau \to 1 \), because of the first term in the brackets. This means that at late times (\( \tau \to 1 \)) the right-hand sides of Equations (19) and (20) are both dominated by the second term, \( d \ln q/d \rho_0 \). Consequently, as long as it is finite, the slope of the initial PDF has very little influence on the late-time evolution of the high-density tail. Finally, the last term in Equation (20) is given by
\[ \frac{d \ln \rho/\rho_0}{d \rho_0} = -\frac{a \tau^2}{\rho_0(1 - \tau^2)}. \] (22)
The slope of the high-density tail of the PDF at time \( t \) is calculated by multiplying the individual terms and taking the limit for \( \tau \to 1 \). As long as the slope of the initial PDF is finite, this yields slopes
\[ \lim_{\tau \to 1} \frac{d \ln P_V}{d \ln \rho} = -\frac{1}{a} - 1, \] (23)
\[ \lim_{\tau \to 1} \frac{d \ln P_M}{d \ln \rho} = -\frac{1}{a}. \] (24)

Hence, at late times the tail of the PDF has a universal slope, independent of the slope of the initial PDF, provided this is finite. Substituting \( a = 1.8614 \), the slopes of the tail are \(-1.54\) for \( P_V \), and \(-0.54\) for \( P_M \).

It is remarkable that the slope of the initial PDF does not influence the slope of the tail at late times. This can be understood by examining the evolution of a discretized bin of the PDF (see Figure 2). Moving from low to high densities, the width of the bin is stretched. Rewriting Equation (16) as a function of density contrast \( \rho/\rho_0 \) (see Equation (7)), and computing the limit for large density contrast, we obtain
\[ q^{-1} \propto (\rho/\rho_0)^{1/a+1} \approx (\rho/\rho_0)^{1.54}. \] This means that the initial slope is stretched over \( \approx 1.5 \) orders of magnitude for every order of magnitude that the density contrast increases. Thus, initial features of the PDF are stretched out and become negligible by the time gas reaches high density. What remains is then the result of how bins are stretched. This stretching is given solely by the intrinsic properties of gravity, encrypted in the parameter \( a \).

We illustrate this in Figure 3, where we plot late-time density PDFs for two different initial functions, one starting with a

![Figure 3](https://example.com/figure3.png)  
**Figure 3.** Evolved density PDFs. The PDF in the left plot started as a log-normal. The PDF in the right plot started as a sine wave. Independent of the initial functional form, the PDFs develop a power-law tail at high densities. The slopes of the fits are in good agreement with the analytic solution.
log-normal PDF, and one with a sinusoidal PDF, where we followed the evolution according to our approximate relations (Equations (6) and (7)). In addition, we perform a Monte Carlo simulation of independent collapsing spheres. We set up an ensemble of spheres with initial radii \( r_i(t = 0) \) and densities \( \rho_i(t = 0) \) such that the combined density PDF is log-normal. The number of spheres is varied from 10⁴ to 10⁷ per ensemble. We then let the spheres start to collapse simultaneously and follow the time evolution of the radius according to Equation (6) and the density according to Equation (7). Spheres with higher initial density collapse quickly leading to the formation of the power-law tail as expected. Once a sphere \( j \) with initial density \( \rho_{j,0} \) has collapsed entirely \( (t_{\text{sim}} \geq t_{\text{ff}}(\rho_{j,0})) \), we exclude it from the ensemble. Figure 4 shows the measured PDFs after \( \sim 10\% \) of the gas is collapsed. After an initial formation phase (see Figure 9) the tail of the PDFs shows the expected slope until the majority of the spheres have collapsed and the distribution is dominated by fluctuation effects due to small number statistics.

3.3. Link between Analytic Model and Turbulent Unstable Gas

Up to this point, we only considered the spherically symmetric collapse of a sphere with uniform density and the collapse of an ensemble of spheres in the Monte Carlo simulation, respectively. However, both real as well as simulated systems of gravitationally unstable gas are more complicated. There are many physical aspects that influence the gaseous region such as turbulence, self-gravity, magnetic fields, chemical, or thermal effects. As the main assumption of our model is the condition of free-fall, we need to discuss whether this condition is fulfilled in real and simulated systems, respectively.

One of the most important processes in the fragmentation of a gaseous region is turbulence (Elmegreen & Scalo 2004; Scalo & Elmegreen 2004; Mac Low & Klessen 2004; Hennebelle & Falgarone 2012). Turbulent motions create a hierarchy of structures that break up ordered systems into smaller subsystems. Turbulent regions are therefore not spherically symmetric and do not have uniform density distributions as a whole. Rather, they form elongated structures with local overdensities as demonstrated by Figure 5, a column density snapshot from a hydrodynamical simulation of self-gravitating turbulent gas. The large-scale supersonic motions break up and cascade down to transonic motions in the dense cores, which is confirmed by theory as well as observations (e.g., Larson 1981; Bergin & Tafalla 2007). Once the densest cores start collapsing by passing...
the Jeans instability (see Appendix A), the collapse from cores
down to stars, i.e., the star formation process, occurs within a
free-fall time. Although the individual fragmentation of cores
is still a matter of debate, there is a consensus that the collapse
time scale in real and simulated systems is the free-fall time
(e.g., Krumholz et al. 2005; Padoan et al. 1997; Hennebelle &
Chabrier 2008; Shadmehri & Elmegreen 2011; Hennebelle &
Falgarone 2012). Thus, it seems appropriate to apply a free-fall
model.

Apart from the fact that cores collapse in free-fall one can
ask whether the fragments of a collapsing sphere can again
be described by a sphere, i.e., whether the fragmentation in
this idealized picture is self-similar. Hunter (1962) found that
perturbations in the density structure of a uniform sphere lead
to fragmentation of the sphere and that all perturbing wavelengths
grow equally. The resulting fragmented structure will thus
depend on the Fourier transform of the perturbation field. If one
assumes perturbations of equal amplitude in random directions,
the resulting pattern in real space reveals clumpy roundish
structures. Falle (1972) extended the work by Hunter (1962)
and investigated the fragmentation of a uniform spheroid. They
conclude from a linear perturbation analysis that the spheroid
most likely fragments by slicing parallel to the axis. The lack
of spherical symmetry also leads to the conclusion that the
dominant perturbations are of the order of the Jeans length or
larger, resulting in a small number of large fragments rather
than in a large number of small fragments. All together it seems
reasonable to assume that the collapsing and fragmenting sphere
breaks up into large clumpy objects that are unstable themselves,
i.e., that the fragmentation can be assumed roughly self-similar.

3.4. Comparison to Hydrodynamic Simulations

The slope of the tail of the PDF has been measured in
numerical simulations of turbulent self-gravitating clouds. In the
high-density collapsing regime the PDF is observed to subscribe
to a power-law, PDF($\rho$) $\propto \rho^\mu$. The slope was measured for
the first time by Slyz et al. (2005) who found $\mu = -1.5$, which agrees very well with our analytic prediction. High-
resolution simulations by Kritsuk et al. (2011) reveal a slope of
$\mu = -1.67$ at intermediate to high densities, and $\mu = -1.5$
at very high densities. Recently, Collins et al. (2011) have
performed simulations of magnetized clouds, and find slopes
ranging from $\mu = -1.64$ to $\mu = -1.80$, steeper than in the
purely hydrodynamic case; the stronger the magnetic field, the
steeper is the tail of the PDF.

We can understand this behavior qualitatively by investigating
the influence of the parameter $a$. Although $a$ is introduced as a
simple mathematical device, to match the approximate function
(Equation (5)) to the true collapse solution, we can mimic other
physical effects by changing its value. Figure 6 shows the radius
of the collapsing sphere, and its time derivative, as a function
of time for different values of $a$. It would be ideal to have a
complete description and derivation of the slope of the PDF as a
function of initial collapse velocities incorporated in the initial
differential Equation (1). However, the simple approximation
and the subsequent derivative of the slope of the PDF is not
possible any more in an analytic way. We therefore stick to this
crude approximation to Newton’s law.

For $a < 1.8614$, the collapse is delayed initially, but speeds
up toward the end. This is qualitatively what happens in
marginally unstable density regimes, where the early phase of
the collapse is still influenced by stabilizing effects like thermal
pressure or magnetic fields. At later stages of the collapse,
gravity becomes increasingly dominant. Hence, structures with
different densities are influenced differently by stabilizing
effects. The collapse of gas with initial density $\rho_i$ is more
strongly delayed than the collapse of gas with initial density
$\rho_j > \rho_i$. This results in a larger stretching of the density bin
$\Delta \rho = \rho_j - \rho_i$, compared with the case of free-fall. The larger
the stabilizing effects, e.g., the magnetic field strength (Collins
et al. 2012), the larger is the stretching and the steeper the tail.

Conversely, the tail is shallower if collapse is faster than
pure free-fall. This is the case in converging flows, where the
collapse does not start with zero velocity, but instead with an
initial converging velocity field (Ballesteros-Paredes et al. 2003;
Klessen et al. 2005; Banerjee et al. 2009).

4. CONNECTION BETWEEN THE PDF
AND MASS ACCRETION

4.1. Derivation of the Accretion Rate

The mass accretion rate is defined as the rate at which
mass evolves above a threshold density $\rho_{\text{accr}}$. In the free-fall
approximation this is

$$M_{\text{accr}}(t) = \frac{dM}{d\rho} \bigg|_{\rho_{\text{accr}}} \frac{d\rho}{dt} \bigg|_{\rho_{\text{accr}}} ,$$

and the problem is to evaluate the derivatives on the right side
of Equation (25), as functions of $\rho_{\text{accr}}$ and $t$. 

Figure 6. Left: dimensionless radius against dimensionless time, for different values of $a$. Right: corresponding plots of dimensionless inward radial velocity against dimensionless time. Large values for $a$ mimic a delayed collapse that speeds up toward the end. Small values of $a$ accelerate the collapse early on.
Following the argument in Section 3.1 allows us to express the first term on the right hand side as a function of \( P_M(t_1) \), where \( t_1 \) corresponds to the time, when the gas reached the density \( \rho_{\text{accr}} \). It is important to note that the bins of constant volume in Figure 2 do not conserve mass over time. The first term on the right side of Equation (25) therefore needs to be adjusted to ensure mass-conservation of the system. The mass of the bin increases by a factor of \( M_1/M_0 \) which we have to correct for yielding

\[
\frac{dM}{d\rho} \bigg|_{\rho_{\text{accr}}} = \frac{M_0}{M_1} P_M(t_1) \tag{26}
\]

\[
= \frac{\rho_0}{\rho_1} P_M(t_1) \tag{27}
\]

\[
= P_M(t_0) \frac{\Delta \rho_0}{\Delta \rho_1}. \tag{28}
\]

In order to determine the rate at which mass evolves above \( \rho_{\text{accr}} \) at time \( t \), we need to solve for the initial density \( \rho_0 \) that evolves to \( \rho_{\text{accr}} \) at this time, i.e., to solve \( \rho(\rho_0, t) = \rho_{\text{accr}} \) and obtain \( \rho_0(\rho_{\text{accr}}, t) \). If we set \( a = 1.8614 \), Equation (7) cannot be inverted analytically to obtain \( \rho_0(\rho_{\text{accr}}, t) \). However, if we set \( a = 2 \) (which still only deviates from the exact collapse solution by less than 4%, see Figure 1), Equation (7) becomes

\[
\rho_s(\rho_0, t) = \rho_0(1 - Q \rho_0 t^2)^{-2}, \tag{29}
\]

and can be inverted analytically to give

\[
\rho_0(\rho_s, t) = \frac{2Q \rho_s t^2 + 1}{2Q^2 \rho_s t^4} + \sqrt{\left(\frac{2Q \rho_s t^2 + 1}{2Q^2 \rho_s t^4}\right)^2 - \frac{1}{Q^2 t^4}}. \tag{30}
\]

This solution for \( \rho_0(\rho_s, t) \) can then be used to calculate \( P_M \) (Equation (26)) and the deviation arising from using the approximate solution (Equation (5)) with \( a = 2 \), in place of the exact solution (Equation (4)). The dip in the lower plot is due to the switch from a positive to a negative deviation.

4.2. Log-normal Density PDFs

Although according to our approximation the high density slope is unaffected by the functional details of the initial PDF, we need to adopt an initial functional form of the PDF in order to apply the free-fall model to the accretion rate of a collapsing system.

Isothermal non-self-gravitating gas develops a log-normal PDF in response to driven supersonic turbulence (see Section 1). Although astrophysical systems are often not isothermal and are always self-gravitating, a significant fraction of the interstellar medium is dominated by kinematic motions. Under this circumstance, thermal effects and self-gravity play a minor role, and the density PDF approaches to a log-normal form (Mac Low & Klessen 2004; Elmegreen & Scalo 2004; McKee & Ostriker 2007; Goodman et al. 2009; Kainulainen et al. 2009). This overall highly dynamical state of clouds and cloud complexes seems to be in contrast to our model of collapsing spheres from rest. However, the large scale turbulent motions cascade down to transsonic or even subsonic motions, such that many of the dense cores that populate the high-density extreme of the PDF appear to start their collapse from relatively quiescent initial conditions, in which the turbulence is at best transsonic (e.g., Bergin & Tafalla 2007). Our assumption of a negligible net effect of the initial turbulence on the contraction of the spheres is clearly a deficiency that needs to be extended in a future work with a more general theory. However, as it is unclear to what extent the turbulence results in a net initial contraction or expansion, we apply our model to the log-normal density PDF, viz.

\[
P(\rho) \propto \exp\left(- \frac{(\ln(\rho/\langle \rho \rangle) - \ln(\rho_{\text{peak}}/\langle \rho \rangle)^2}{2\sigma^2}\right), \tag{31}
\]

with variance

\[
\sigma^2 = \ln(1 + b^2 M^2) \tag{32}
\]

\[
= \ln(1 + 3 M_{\text{comp}}'), \tag{33}
\]

and peak density

\[
\ln\left(\frac{\rho_{\text{peak}}}{\langle \rho \rangle}\right) = -\frac{\sigma^2}{2}. \tag{34}
\]

The variance, \( \sigma^2 \), can be related to the dynamics of the system in two different ways. In the first one (see Equation (32)), the empirical parameter \( b \) depends on the nature of the turbulence. Federrath et al. (2010) have investigated driven turbulence, and find \( b = 1/3 \) for purely solenoidal driving and \( b = 1 \) for purely compressive driving. Here, the quantity \( M = \nu_{\text{rms}}/c_s \) is the rms Mach number of the turbulence. In the second one (see Equation (33)), the best fit value for the empirical parameter \( \gamma \) is \( \gamma = 1.7 \) and \( M_{\text{comp}} = \nu_{\text{comp, rms}}/c_s \) is the Mach number of the compressive motions (Konstandin et al. 2012b). To begin with, we set \( b \) to unity and vary the dynamics via the Mach number, \( M \). We use normalized units with respect to the average density \( \langle \rho \rangle \).

Figure 8 illustrates \( P_M \), and cumulative distributions \((\int_{\rho_{\text{min}}}^{\rho} P(\rho')d\rho')\), for different values of the standard deviation, \( \sigma \). The mass distributions of the log-normal PDFs are highly asymmetric, in the sense that there is very little mass at densities \( \rho < \rho_{\text{peak}} \) for large \( \sigma \). Table 1 records the peak density, the fraction of mass below the peak, and the density \( \rho_{50\%} \) at which
the integral \( \int_{\rho}^{\rho_{\text{peak}}} P(\rho') d\rho' = 0.5 \). These numbers are critical to understanding how the accretion rate varies with time.

One limitation of the model developed here is that we invoke, ab initio, a cloud having a log-normal density PDF, corresponding to a cloud without self-gravity, and we do not specify how such a cloud might have been assembled. This cloud is then assumed to undergo free-fall collapse. As a result, the time evolution of the PDF, especially at early times, may show artificial features that should not be expected, either in observations, or in numerical simulations, i.e., features that would not arise if the cloud were assembled self-consistently in the presence of self-gravity. How strong these features are depends on the density regime we are investigating. Very dense regions with \( \rho \gg \langle \rho \rangle \) will collapse on very short time scales compared to the global characteristic time scale of the cloud, transforming the very steep fall-off of the log-normal density PDF into the relatively slow fall-off of the power-law tail. In contrast, gas at densities far below the peak, \( \rho \ll \langle \rho \rangle \), will not be affected, because the free-fall time of this gas is very long compared to the evolutionary time scales with which we are concerned.

Figure 9 illustrates how the power-law tail is established. We define the tail as the part of the PDF that is noticeably above the approximately log-normal part (this transition is located by eye, and marked with a small vertical line on Figure 9), and the power-law tail is the part that has asymptoted to the universal slope given by Equation (24). After 0.01\( t_{ff}(\rho) \) the tail starts above \( \sim 10^{2.5} \rho_{\text{peak}} \), and the power-law tail starts above \( \sim 10^{2} \rho_{\text{peak}} \) (this falls outside Figure 9). After 0.04\( t_{ff}(\rho) \), the power-law tail starts above \( 10^{2} \rho_{\text{peak}} \). The reason why the switch from a log-normal PDF to a power-law tail advances steadily to ever lower densities is the highly nonlinear nature of gravitational collapse, which starts very slowly and speeds up rapidly toward the end. Consequently, the impact of free-fall on the density PDF at density \( \rho_{s} \) can only manifest itself after \( \sim t_{ff}(\rho_{s}) \), and we should expect the power-law tail to be well-defined above a density \( \rho_{\text{tail}}(t) \) given by

\[
\rho_{\text{tail}}(t) \sim \left( \frac{t}{t_{ff}(\rho_{s})} \right)^{-2}. \tag{35}
\]

Measurements of \( \rho_{\text{tail}}(t) \) based on Figure 9 are indeed well fitted by

\[
\rho_{\text{tail}}(t) \approx 0.2 \left( \frac{t}{t_{ff}(\rho_{s})} \right)^{-2.0}. \tag{36}
\]

Thus, for a given density, \( \rho_{s} \), the tail starts to deviate from the log-normal distribution at roughly 0.45\( t_{ff}(\rho_{s}) \), when the density has increased by \( \sim 50\% \) (see Equation (7)).

The fraction of the total mass in the tail (i.e., above the density indicated by the vertical line in Figure 9) is shown at the ends of the arrows on Figure 9. After 0.15\( t_{ff}(\rho_{s}) \) already \( \sim 70\% \) of the mass is in the tail. Above a certain threshold density, \( \rho_{\text{accr}} \), we can infer that the gas has condensed into stars, and so the total fraction of gas above \( \rho_{\text{accr}} \) gives the star formation efficiency (SFE), and the rate at which mass evolves above \( \rho_{\text{accr}} \) gives the SFR.

4.3. Dependence of the Accretion on the Threshold Density

Both the SFE and the SFR depend on the threshold density, \( \rho_{\text{accr}} \). To illustrate this, we set \( \mathcal{M} = b = 1 \) and vary the threshold density in units of \( \sigma \) from 1 \( \sigma \) to 5\( \sigma \). Figure 10 shows the SFR and the SFE, both as functions of time, for different threshold densities. The time axis is normalized to the free-fall time of the average density.
Figure 10. Star formation rate and star formation efficiency for different accretion threshold densities $\rho_{\text{accr}}$. For $\rho_{\text{accr}} \geq 5\sigma$ the star formation efficiencies are indistinguishable.

Table 2: Key Properties of the Evolution of the Power-law Tail

| $t/t_{\text{ff}}(\langle \rho \rangle)$ | $\rho_{\text{tail}}/\langle \rho \rangle$ | $m_{\text{tail}}$ | SFE$_5$ | SFE$_6$ | SFE$_7$ |
|--------------------------------------|--------------------------------------|----------------|--------|--------|--------|
| 0.01                                 | 300                                  | 0.007          | 8.0 x $10^{-5}$ | 4.0 x $10^{-5}$ | 4.0 x $10^{-5}$ |
| 0.04                                 | 30                                   | 0.17           | 0.025  | 0.024  | 0.023  |
| 0.15                                 | 3                                    | 0.70           | 0.35   | 0.35   | 0.35   |
| 0.40                                 | 0.3                                  | 0.97           | 0.78   | 0.78   | 0.78   |

Notes. Column 1 gives the time, $t$, in units of $t_{\text{ff}}(\langle \rho \rangle)$. Column 2 gives the density, $\rho_{\text{tail}}$, above which the density PDF diverges markedly from log-normal portion (i.e., the tail, see Figure 9), in units of $\langle \rho \rangle$. Column 3 gives the mass fraction, $m_{\text{tail}}$, above $\rho_{\text{tail}}$. Columns 4–6 give the star formation efficiencies, SFE$_n$, corresponding to different $\rho_{\text{accr}} = 10^n(\langle \rho \rangle)$, for $n = 5, 6, \text{and } 7$.

The initial SFR is significantly higher for lower $\rho_{\text{accr}}$, because, if $\rho_{\text{accr}}$ is low, there is more gas just below $\rho_{\text{accr}}$ poised ready to evolve above $\rho_{\text{accr}}$. However, the SFR at late times is only weakly dependent on $\rho_{\text{accr}}$, and in all cases it peaks at $\sim t_{\text{ff}}(\langle \rho \rangle)/2$. The SFE only counts gas that passes the threshold density $\rho_{\text{accr}}$ during the evolution, not the gas that is already located in regions with $\rho > \rho_{\text{accr}}$ at the outset. Thus, in the case with $\rho_{\text{accr}}/\langle \rho \rangle = 1\sigma$, roughly $10\%$ of the gas is initially denser than $\rho_{\text{accr}}$, and consequently the SFE saturates at $\text{SFE} \approx 0.9$.

Provided that we set $\rho_{\text{accr}}$ sufficiently high, the SFE is very weakly dependent on $\rho_{\text{accr}}$. Table 2 records, as a function of the time, $t$, the density, $\rho_{\text{tail}}$, at which the tail departs markedly from the log-normal portion (see Figure 9), the fraction of the total mass, $m_{\text{tail}}$, that is in the tail, and the star formation efficiencies, SFE$_n$, corresponding to different $\rho_{\text{accr}} = 10^n(\langle \rho \rangle)$, for $n = 5, 6, \text{and } 7$.

4.4. Predicted Star Formation Rates

We define the normalized SFR, using the free-fall time at the average density and total mass, viz.,

$$SFR(t) = \frac{\dot{M}(t)_{\text{ff}}(\langle \rho \rangle)}{M_{\text{tot}}}, \quad (37)$$

and the mean normalized star formation rate as $\langle SFR \rangle = \text{SFE}(t)/t$. Figure 11 shows the time evolution of (a) the SFE, (b) the normalized SFR, and (c) the mean normalized SFR, for different widths of the initial density PDF. The gray shaded band indicates the range of observed average SFRs (see next section). In more quiescent regions it takes much longer for star formation...
We take molecular cloud data from Heiderman et al. (2010), normalized mean star formation rate, is too slow to be observed. Instead we have to compare the measure because the time evolution of molecular cloud cores of time, $SFR(t)$, is in theory suitable for comparing with observations, namely the volume-density PDF, in particular the tail, and the $SFR$ as a function of normalized time $t/t_\text{ff}$. For $M = 5$ and $M = 20$, the model number is much earlier and the peak SFRs are perceptibly higher. Significant fractions of the cloud are accreted on very short time sets in much earlier and when it finally does, the rate is very low. For $M = 88$, for pure solenoidal driving, there is a logarithmic scaling with the density, $\mu \equiv \frac{d \ln V}{d \ln \rho} = -\frac{3}{p}$; further details are shown in the Appendix. Hence, the slope of the tail of the volume-weighted PDF, $\mu = -1.54$, transforms into $p = -1.95$, which is very close to the density exponent for a singular isothermal sphere, $p = -2$ at the beginning of the collapse (before the rarefaction wave changes the index of the profile to $p = -1.5$; Shu 1977).

For an observer looking along the $z$-axis, the column-density profile is then

$$\Sigma(x, y) = \int_{-\infty}^{\infty} \rho(x, y, z) dz$$

$$= \frac{\sqrt{\pi}}{\alpha} \frac{\Gamma\left(\frac{p-1}{2}\right)}{\Gamma\left(\frac{p}{2}\right)} \frac{1}{(x^2 + y^2)^{p/2}}. \quad (40)$$

where $\Gamma$ is the Gamma function. In terms of the impact parameter on the observer’s sky, $s = \sqrt{x^2 + y^2}$, this reduces to

$$\Sigma(s) = \frac{1}{\alpha^2 s^{p-1}}. \quad (41)$$

From this we can derive the column-density PDF with the corresponding logarithmic scaling of

$$\eta \equiv \frac{d \ln A}{d \ln \Sigma} = -\frac{2}{p - 1}. \quad (42)$$

If we eliminate $p$ between Equation (39) for $\mu$ (the slope of the high-density tail of volume-density PDF) and Equation (42) for $\eta$ (the slope of the high-density tail of column-density PDF), we obtain

$$\mu \equiv \frac{3\eta}{2 - \eta}; \quad \eta = \frac{2\mu}{3 + \mu}. \quad (43)$$

Hence, the power-law tail that we predict for the volume-density PDF translates into a power-law tail on the column-density PDF.

5. COMPARISON TO OBSERVATIONS

Among the quantities we compute from our model, two are in theory suitable for comparing with observations, namely the density PDF, in particular the tail, and the $SFR$ as a function of time, $SFR(t)$. However, $SFR(t)$ is in practice impossible to measure because the time evolution of molecular cloud cores is too slow to be observed. Instead we have to compare the normalized mean star formation rate, $\langle SFR \rangle$, with observations. We take molecular cloud data from Heiderman et al. (2010), covering the mass range $10^4 M_\odot$ to $10^6 M_\odot$ and SFRs from $\sim 1$ to $\sim 30 M_\odot \text{Myr}^{-1}$. From their data we estimate normalized mean SFRs ranging from $\sim 10^{-4}$ to $\sim 10^{-1}$, as indicated by the gray band on panel (c) of Figure 11. In all cases the average values are consistent with the model in the very early stage of the collapse, i.e., for a very low SFE.

As a volume-density PDF cannot be observed, we need to transform the volume-density PDF into a column-density PDF. This transformation will in general reduce the amount of information, due to projection effects, and so it is not normally possible to restore the volume-density PDF from the column-density PDF, without making assumptions about the underlying geometry of the cloud. This problem has been addressed in detail by, e.g., Brunt et al. (2010), Burkhart & Lazarian (2012), and Ginsburg et al. (2013).

For simplified cases, one can directly compute the volume- and column-density PDFs from the density distribution. Specifically, if we assume a spherically symmetric power-law density distribution with exponent $\rho$,

$$\rho(r) = \frac{1}{\alpha} r^{-p}, \quad (38)$$

there is a logarithmic scaling with the density,

$$\mu \equiv \frac{d \ln V}{d \ln \rho} = -\frac{3}{p}; \quad (39)$$

Figure 12 shows the SFE, and the normalized SFR for all four cases. As expected, a higher compressive Mach number leads to a broader density PDF, faster star formation, and a higher SFR.
The relationship between $\eta$ and $\mu$ is plotted on Figure 13.

Kainulainen et al. (2009) have investigated the structure of molecular clouds, using IR extinction maps, and find a strong correlation between the power-law tail on the column-density PDF and the star formation activity in the cloud. Using their Figure 4, we estimate that the tail of the column-density PDF has slope in the range $-2.3 \lesssim \eta \lesssim -1.8$. This range is represented by a shaded vertical band on Figure 13, and corresponds to a volume-density PDF with slope in the range $-1.6 \lesssim \mu \lesssim -1.4$, in very good agreement with the prediction of our free-fall analysis.

Schneider et al. (2012) have observed the Rosette molecular cloud and extracted column-density PDFs for the entire cloud, and also for individual regions. The global column-density PDF (their Figure 6) has a power-law tail with slope $\eta \simeq -3.0$, corresponding to retarded collapse and a volume-density PDF with a power-law tail having slope $\mu \simeq -1.8$. The steep slopes of these column-density and volume-density PDFs suggest that the cloud as a whole is not undergoing free-fall collapse, but rather retarded contraction. It is not necessary that the whole cloud be contracting. Splitting the cloud into subregions reveals that the dynamics can be quite different from one subregion to another (see their Figures 2 and 3). The column-density PDF for the central region (3) shows a flat power-law tail at high column-densities, with slope $\eta \simeq -1.5$, corresponding to free-fall conditions. In contrast, the column-density PDF for the quiescent region (6) appears not to be contracting at all.

6. SUMMARY AND CONCLUSION

We have developed an analytic description for the evolution of the density PDF, based on free-fall collapse of a sphere. We use a simple analytic approximation to describe the collapse in closed functional form. From this we derive the slope of the high-density tail of the density PDF, and the SFR as a function of time. Our results can be summarized as follows.

1. In the freefall approximation, the high-density tail of the density PDF asymptotes to a power-law with slope $P_\nu(\rho) \propto \rho^{-1.54}$ for the (volume-weighted) density PDF, and $P_\mu(\rho) \propto \rho^{-0.54}$ for the mass-weighted equivalent. The only condition is that the initial density PDF at the beginning of the collapse is known, the SFE can be related to the threshold density at which the high-density tail begins.

2. Physical processes that retard the collapse in marginally unstable density regimes, such as thermal pressure or magnetic fields, steepen the slope of the high-density tail. Although these retarding processes are not explicitly included in our analysis, we can mimic them by varying the parameter $a$ in the approximate collapse solution. Conversely, processes that accelerate the collapse, relative to free-fall, such as driven converging flows, flatten the high-density tail of the PDF.

3. We derive analytic descriptions for the free-fall accretion rate, based on the density PDF. The corresponding SFRs are highly sensitive to the initial width of the density PDF. Star-forming regions with low turbulent motions, corresponding to narrow density PDFs, lead to retarded star formation and low SFRs. In contrast, highly turbulent systems, corresponding to broad density PDFs, result in an early and fast star formation process, i.e., a bursting mode of star formation.

4. Comparisons to observations of star-forming regions are in reasonably good agreement with our model. The observed SFRs are consistent with the model during the early stages of collapse, i.e., for a very low SFE. Assuming that observed clouds approximate to spherical symmetry, the power-law tails of their column-density PDFs suggests that they are contracting with speeds close to free-fall.

We thank Steffi Walch and Christoph Federrath for useful comments and inspiring discussions. We also thank the referee for careful reading of the manuscript and detailed comments, which improved the manuscript perceptibly. P.G., L.K., and R.S.K. acknowledge subsidies from the Baden-Württemberg-Stiftung via contract research in the program Internationale Spitzenforschung II (grant P-LS-SPII/18). R.S.K. furthermore gives thanks for subsidies from the Deutsche Forschungsgemeinschaft (DFG) via the SFB 881 ‘The Milky Way System’ (subprojects B1, B2, and B5), as well as via the SPP 1573 grant (KL 1358/14-1).

APPENDIX A

THERMODYNAMICS

We can estimate the stability of a cloud with the Jeans analysis. The critical mass above which thermal effects cannot prevent the gravitational collapse is the Jeans mass (Jeans 1902),

$$M_J = \frac{\pi^2}{6} \left( \frac{\kappa_B}{G\mu m_p} \right)^{3/2} \frac{T^{3/2}}{\rho^{1/2}},$$

computed as a sphere with the diameter of the Jeans length, $\lambda_J = \sqrt{\pi} k_B T/(\mu m_H)$, where $k_B$ is Boltzmann’s constant, $T$ the
temperature, \( \mu \) the molecular weight of the gas, \( m_H \) the mass of a hydrogen atom, and \( \rho \) the average density of the cloud. The important relation to note is the dependency of the Jeans mass on the temperature and the density. In molecular clouds, the temperature decreases with increasing density as shown in Figure 14 up to a density of \( \rho \sim 10^{-18} \text{ g cm}^{-3} \) and stays roughly constant above that threshold up to a density of \( \rho \sim 10^{-12} \text{ g cm}^{-3} \). As a result, the Jeans mass decreases with a scaling of \( M_J \propto \rho^{-0.9} \) below \( \rho \sim 10^{-18} \text{ g cm}^{-3} \) and \( M_J \propto \rho^{-0.4} \) between \( 10^{-18} \text{ g cm}^{-3} < \rho < 10^{-12} \text{ g cm}^{-3} \). For a non-fragmenting cloud with constant mass this means that the cloud becomes more unstable during the collapse and the assumption of free-fall collapse becomes more appropriate during the collapse. If a cloud fragments into many subsystems and the mass of the individual fragments decreases faster due to fragmentation than the density increases due to the collapse, the free-fall approximation eventually breaks. Depending on the degree of fragmentation, our analysis might break down for certain systems. However, the fragmentation of clouds is a subject on its own as it depends on the properties of the turbulence, the physical processes involved, and the initial conditions, which goes beyond the scope of this paper. At this point, we therefore stick to the simplified Jeans analysis and the conclusions concerning the stability.

APPENDIX B

PDFs FOR SPHERICALLY SYMMETRIC DENSITY DISTRIBUTIONS

For a spherically symmetric power-law density distribution with exponent \( p \),

\[
\rho(r) = \frac{1}{\alpha r^p},
\]

the (volume-weighted) density PDF takes the form

\[
\frac{dV}{d\rho} = - \frac{4\pi}{p} \alpha^{-3/p} \rho^{-3/p-1},
\]

and mass-weighted equivalent

\[
\frac{dM}{d\rho} = - \frac{4\pi}{p} \alpha^{-3/p} \rho^{-3/p}.
\]

Hence, there is a logarithmic scaling with the density,

\[
\mu \equiv \frac{d \ln V}{d \ln \rho} = -\frac{3}{p},
\]

and

\[
\frac{d \ln M}{d \ln \rho} = -\frac{3}{p} + 1,
\]

respectively. The projected column density distribution reads

\[
\Sigma(s) \approx \frac{1}{\alpha/3^{2/3}}.
\]

From this we can derive the area-weighted column-density PDF,

\[
\frac{dA}{d\Sigma} = - \frac{2\pi}{p-1} \alpha^{-2/(p-1)} \Sigma^{-2/(p-1)-1},
\]

and mass-weighted column-density PDF,

\[
\frac{dM}{d\Sigma} = - \frac{2\pi}{p-1} \alpha^{-2/(p-1)} \Sigma^{-2/(p-1)-1};
\]

The corresponding logarithmic scalings are

\[
\eta \equiv \frac{d \log A}{d \log \Sigma} = -\frac{2}{p-1},
\]

and

\[
\frac{d \log M}{d \log \Sigma} = -\frac{2}{p-1} + 1.
\]
