The reference chiral helimagnet MnSi is the first system where Skyrmion lattice correlations have been reported. At a zero magnetic field the transition at $T_C$ to the helimagnetic state is of first order. Above $T_C$, in a region dominated by precursor phenomena, neutron scattering shows the buildup of strong chiral fluctuations over the surface of a sphere with radius $2\pi/\ell$, where $\ell$ is the pitch of the helix. It has been suggested that these fluctuating correlations drive the helical transition to first order following a scenario proposed by Brazovskii for liquid crystals. We present a comprehensive neutron scattering study under magnetic fields, which provides evidence that this is not the case. The sharp first order transition persists for magnetic fields up to 0.4 T whereas the fluctuating correlations weaken and start to concentrate along the field direction already above 0.2 T. Our results thus disconnect the first order nature of the transition from the precursor fluctuations. They also show no indication for a tricritical point, where the first order transition crosses over to second order with increasing magnetic field. In this light, the nature of the first order helical transition and the precursor phenomena above $T_C$, both of general relevance to chiral magnetism, remain an open question.

DOI: 10.1103/PhysRevLett.119.047203

In cubic chiral helimagnets such as MnSi, chiral Skyrmions are stabilized under a magnetic field and form a lattice in the so-called A phase, a small pocket in the temperature-magnetic field phase diagram just below the critical temperature $T_C$ [1]. These Skyrmions are topologically protected vortexlike spin textures that have been observed both in reciprocal space by neutron scattering and in real space by Lorentz transmission microscopy [1–7].

The helical transition at zero magnetic field is of first order [8–12] and preceded by strong chiral fluctuating correlations. These build up just above $T_C$ leading to intense diffuse scattering of neutrons that spreads homogeneously on the surface of a sphere with radius $r = 2\pi/\ell$, with $\ell$ being the pitch of the helix [13]. This peculiar scattering occurs in a region dominated by precursor phenomena that have been probed with a wide range of experimental techniques [9–11,14–16]. Similar precursor phenomena have also been found in FeGe [17,18] and the multiferroic Cu$_2$OSeO$_3$ [19–21] and are thus of general relevance to chiral magnetism.

It has been suggested that the precursor fluctuating correlations drive the helical transition to first order [12] according to a scenario originally proposed by Brazovskii for liquid crystals [22]. This approach provides a good description of the temperature dependence of the correlation length and the susceptibility in MnSi [12]. However, it does not satisfactorily describe all observations [16] and is less conclusive for other chiral magnets such as Cu$_2$OSeO$_3$ [21] and Fe$_{0.7}$Co$_{0.3}$Si [23]. Thus the origin of the first order phase transition in helimagnets and its connection to the fluctuating correlations and precursor phenomena above $T_C$ is still an open question that is addressed in this Letter for the case of MnSi. For this purpose we combined small angle neutron scattering (SANS) and neutron spin echo (NSE) spectroscopy to monitor the influence of a magnetic field on both the phase transition and the fluctuating correlations. The experimental results show that the fluctuations are no longer isotropic for $B \gtrsim 0.2$ T whereas the sharp first order transition persists up to at least $B \sim 0.4$ T. It appears that the first order helical transition and the precursor phenomena are not interrelated as expected by the Brazovskii approach. Consequently, the nature of the first order helical transition and of the precursor phenomena above $T_C$, both of general relevance to chiral magnetism, remains an open question.

The measurements were performed on an almost cubic single crystal of MnSi with dimensions $\approx 5 \times 5 \times 5 \text{ mm}^3$ grown from a stoichiometric melt as described in [9]. The crystal was aligned with the [110] crystallographic axis vertical. The SANS experiments were performed at the time-of-flight instrument LARMOR located at the neutron spallation source ISIS. The neutron beam was unpolarized and contained neutrons with wavelengths of $0.09 \leq \lambda \leq 1.25 \text{ nm}$. The measurements were performed with the
magnetic field applied both along and perpendicular to the incoming neutron beam, designated by the wave vector $\vec{k}_i$, and thus provide a full picture of the magnetic correlations. All SANS patterns were normalized to standard monitor counts and background corrected using a high temperature reference measurement at 40 K.

The NSE experiments were performed at the spectrometer IN15 of the Institute Laue-Langevin, which has a highly polarized incident neutron beam and polarization analysis capabilities but a restricted angular acceptance, as illustrated by the red squares in Fig. 1. The measurements were performed for $\lambda = 0.9$ and 0.8 nm with $\Delta \lambda / \lambda \sim 15\%$. The magnetic field was applied perpendicular to $\vec{k}_i$ using a horizontal field cryomagnet. The NSE spectra were recorded in the ferromagnetic NSE configuration [24,25] and were averaged over the entire detector since no significant $Q$ dependence was found.

SANS measures the static structure factor $S(Q) \equiv S(Q, t = 0)$, with $Q$ being the momentum transfer, which is the spatial Fourier transform of the correlations. For fluctuating correlations decaying exponentially with distance $d$, typically $\sim \exp(-d/\xi)/d$ with $\xi$ being the...
characteristic correlation length, $S(Q)$ assumes the general Ornstein-Zernike form,

$$S(Q) = C/((Q - \tau)^2 + \xi^{-2}). \quad (1)$$

With NSE spectroscopy we directly determined the normalized intermediate scattering function $I(Q, t) = S(Q, t)/S(Q)$, and thus the decay in time of the correlations. The combination of these two neutron scattering techniques provided a complete characterization of the magnetic correlations both in space and in time.

Figure 1(a) depicts typical SANS patterns for $B = 0.2$ T with $\vec{B}||\vec{k}_i$, a configuration that is sensitive to helical modulations perpendicular to the field. Below $T_C$, the sixfold symmetry scattering pattern shows the existence of the Skyrmion lattice [1] on top of a weak ring of diffuse scattering. The ring of diffuse scattering, similar to the symmetry scattering pattern shows the existence of the dent of both the magnetic field and its orientation, and is in the TC phase. The diffuse scattering persists above the onset of the helical Bragg peaks at $\sim 0.4$ T, as displayed in Fig. 1(b). They show that is, sensitive to helical modulations along the field, the ring is hardly visible for $B = 0.35$ T and $B = 0.5$ T, respectively. In the complementary configuration $\vec{B}||\vec{k}_i$, the ring is almost completely suppressed for $B = 0.5$ T [Fig. 1(e)].

Figures 1(g) and (h) depict the total scattered intensity plotted as a function of temperature for $\vec{B}||\vec{k}_i$ and $\vec{B}\perp\vec{k}_i$, respectively. Both figures show that at zero magnetic field the onset of the helical Bragg peaks at $T_C$ leads to a sharp jump in intensity by more than an order of magnitude within $\sim 0.2$ K. Under magnetic field this intensity jump persists but only for $\vec{B}\perp\vec{k}_i$ and $B \leq 0.4$ T. At $B = 0.5$ T this intensity increase occurs gradually over more than 1 K.

In the complementary configuration, for $\vec{B}||\vec{k}_i$, the intensity jump at $T_C$ becomes a cusp with the exception of $B = 0.2$ T, where a maximum marks the Skyrmion lattice phase. For magnetic fields exceeding 0.2 T, the cusp becomes less prominent and disappears for $B = 0.5$ T where the magnetic field suppresses most of the scattering.

The effect of the magnetic field on the fluctuations, seen in the anisotropy of the diffuse scattering discussed above, is also reflected on the deduced correlation lengths, obtained by fitting the radial averaged intensities, given in the supplement, to Eq. (1) convoluted with the instrumental resolution. These are given in Figs. 1(i) and 1(j) for $\vec{B}||\vec{k}_i$ and $\vec{B}\perp\vec{k}_i$, respectively. For $B < 0.2$ T, $\xi$ is independent of both the magnetic field and its orientation, and is in good agreement with the values reported in the literature for zero field [10–12,27]: $\xi$ increases monotonically from $\sim 3$ nm at $T_C + 2$ K up to approximately 16 nm, i.e. the pitch of the helix at $T_C$ [see Supplemental Material [28] Fig. S2(c)]. For $B > 0.2$ T, $\xi$ is no longer isotropic and depends on the magnetic field orientation. For $\vec{B}||\vec{k}_i$, $\xi$ decreases with increasing magnetic field and at 0.4 T it stays practically constant between 29 and 32 K and does not exceed 4 nm. In the complementary configuration, for $\vec{B}\perp\vec{k}_i$, the zero field behavior remains unchanged up to 0.4 T, despite a slight shift of $T_C$ for 0.4 T. At 0.5 T the increase of $\xi$ persists but stretches over a wide temperature range.

We now switch to the NSE results that probed the transition to the conical phase at twelve magnetic fields ($0.12 \leq B \leq 0.5$ T) applied perpendicular to $\vec{k}_i$, a configuration where the chiral correlations do not depolarize the scattered neutron beam [29,30]. We note that for $\vec{B}||\vec{k}_i$ the scattered beam was completely depolarized up to the highest magnetic fields indicating that the probed correlations remain completely chiral and with the same topology as at zero field [10,11].

Figures 2(a) and 2(b) display NSE spectra for $B = 0.24$ T and $B = 0.5$ T, respectively. The intermediate scattering function decays exponentially with a characteristic relaxation time $t_0$ to an elastic fraction $a_{NSE}$ that originates from the elastic contribution of the emerging Bragg peak,

$$I(Q, t) = (1 - a_{NSE}) \exp(-t/t_0) + a_{NSE}. \quad (2)$$

The deduced values for $a_{NSE}$ and $t_0$ are displayed in Figs. 2(c) and 2(d). For all magnetic fields up to 0.4 T, $a_{NSE}$ evolves from $\sim 30\%$ to $100\%$ within 0.2 K following the abrupt appearance of the conical Bragg peaks seen in the increase of the scattered intensity with decreasing temperature displayed in Fig. 1(h). This is quantitatively similar to the zero field behavior [10,11]. A change sets in at 0.5 T where the elastic fraction increases much slower from $\sim 30\%$ to $100\%$ within about 0.8 K.

A complementary picture is found for the relaxation times depicted in Fig. 2(d). For magnetic fields lower than 0.4 T, $t_0$ increases from $\sim 0.4$ ns at $T_C + 1.5$ K to $\sim 1$ ns close to $T_C$, and this is very similar to the behavior observed at zero field [10,11]. At $B = 0.5$ T, on the other hand, where the elastic fraction increase is slower, the temperature dependence of $t_0$ can be followed over a larger temperature range and is more pronounced than at low fields: $t_0$ is as low as 0.1 ns at 27.4 K, where the elastic fraction is already $\sim 20\%$, and increases within 0.8 K by more than an order of magnitude to $\sim 1.2$ ns at $T = 26.6$ K.

Both SANS and NSE show that the zero field sharp first order transition persists up to $B \sim 0.4$ T. At higher magnetic fields the transition becomes gradual but this does not necessarily imply that it crosses over to a second order
transition. This change in behavior occurs indeed when the transition line in the $B$–$T$ phase diagram is no longer vertical [1,31] and might be at least partly attributed to the demagnetization field, which would spread the internal magnetic fields and thus smear the transition. We note that this should not affect the transition at lower fields where the transition line in the $B$–$T$ phase diagram is almost vertical.

The precursor fluctuating correlations above $T_C$ remain chiral also under magnetic fields. However, for $B \geq 0.2$ T they are gradually suppressed and the SANS intensity concentrates along the magnetic field direction. Consequently, the strength and degeneracy in space of the chiral fluctuations are affected by fields almost a factor of 2 weaker than those required to modify the first order nature of the transition. It thus appears that the precursor fluctuations and the first order nature of the transition are separate phenomena and are not accounted for by the Brazovskii approach [12]. Furthermore, the neutron scattering results presented above do not confirm the existence of a tricritical point separating a first order transition, at low magnetic fields, from a second order one at high magnetic fields. The transition remains of first order under magnetic field and is disconnected from the precursor fluctuating correlations above $T_C$. These phenomena, which are both of general relevance to chiral magnetism, are thus not accounted for by the Brazovskii approach [12].

To conclude, neutron scattering does not provide any indication for the existence of a tricritical point separating a first order transition, at low magnetic fields, from a second order one at high magnetic fields. The transition remains of first order under magnetic field and is disconnected from the precursor fluctuating correlations above $T_C$. These phenomena, which are both of general relevance to chiral magnetism, are thus not accounted for by the Brazovskii approach [12].

FIG. 2. Neutron spin echo spectroscopy results. Panels (a) and (b) show the intermediate scattering function $I(Q, t)$ measured at (a) 0.24 and (b) 0.5 T. Panel (c) shows the deduced elastic fractions $a_{\text{NSE}}$ and panel (d) shows the relaxation times $t_0$ as a function of temperature for the magnetic fields indicated.
approach. Their understanding remains an open question calling for novel theoretical approaches in the future.

The authors thank P. Courtois for testing the MnSi single crystal with $\gamma$-ray Laue diffraction and the ISIS and ILL technical support staff for their assistance. They also acknowledge fruitful discussions with U. K. Rössler, M. Mostovoy, G. Blake, and T. Palstra. C. P. and L. B. acknowledge fruitful discussions with U. K. Rössler, M. Schmidt et al., Phys. Rev. B 81, 041203 (2010).
