Abstract

We consider axino warm dark matter in a supersymmetric axion model with R-parity violation. In this scenario, axino with the mass \( m_\tilde{a} \approx 7 \) keV can decay into photon and neutrino resulting in the X-ray line signal at 3.5 keV, which might be the origin of an unidentified X-ray emissions from galaxy clusters and Andromeda galaxy detected by the XMM-Newton X-ray observatory.

I. INTRODUCTION

Various astrophysical and cosmological observations provide convincing evidences for the existence of dark matter (DM). Dark matter distribution spans in wide range of scales from galaxy to clusters of galaxies and the large scale structure of the Universe.

Recently, anomalous X-ray line emissions have been observed from galaxy clusters and also in the Andromeda galaxy [1, 2]. While those might be a result of systematic effects, it would be interesting if the line comes from the new source of astrophysical phenomena or from new physics. It was suggested that the signal might come from decaying dark matter with the mass and lifetime,

\[
\begin{align*}
    m_{\text{DM}} &\simeq 7 \text{ keV}, \\
    \tau_{\text{DM}} &\simeq 2 \times 10^{27} - 2 \times 10^{28} \text{ sec},
\end{align*}
\]

assuming they are the dominant component of dark matter. Some theoretically interesting particle models have been suggested such as sterile neutrino [1, 2], exciting dark matter [4], millicharged dark matter [5, 6], axion like particle [7–9] or in the effective theory [10].

In this paper, we study the warm dark matter axino in a R-parity violating supersymmetric model. With bilinear R-parity breakings, neutralinos mix with neutrinos and thus the axino can decay into photon and neutrino. We find that the axino mass with 7 keV can have the proper lifetime and relic density for the X-ray line emission. In this scenario, as an interesting consequence, the upper bound on the neutrino mass impose that the Bino mass is lighter than about 10 GeV.

In Section II we introduce the model of axino dark matter and in Section III we consider the R-parity violation and decay of axinos. We summarize in Section IV.

II. AXINO DARK MATTER

The strong CP problem and the hierarchy problem in the Standard Model can be naturally solved in the supersymmetric axion model [11, 12]. If axino, the fermionic superpartner of axion, is the lightest supersymmetric particle (LSP), then it is a good candidate of dark matter [13–17]. The effective operator of the axino can be derived by the supersymmetric
transformation of the axion interactions and is given by

$$L_{\text{eff}}^\alpha = i \frac{\alpha_s}{16\pi f_a} \bar{a} \gamma_5 [\gamma^\mu, \gamma^\nu] \tilde{G}^b G^{b\mu
u} + i \frac{\alpha_Y C_a Y^Y}{16\pi f_a} \bar{a} \gamma_5 [\gamma^\mu, \gamma^\nu] \tilde{Y} Y_{\mu\nu},$$  \hspace{1cm} (2)

where $f_a$ is the Peccei-Quinn breaking scale, and $\alpha_s, \tilde{G}, G_{\mu\nu}$ and $\alpha_Y, \tilde{Y}, Y_{\mu\nu}$ are the gauge couplings, gaugino fields and the field strength for $SU(3)_c$ and $U(1)_Y$ gauge groups respectively. The mass of axino is expected to be of the order of gravitino mass, but it can be much smaller \cite{18-23}, or much larger \cite{24} than the typical supersymmetric particle mass scale, depending on the specific models \cite{25}. Here we take the light axino mass of the order of keV as dark matter component.

The primordial axinos are generated from the thermal plasma during reheating after the primordial inflation. If the reheating temperature is lower than the decoupling temperature \cite{13},

$$T_{\text{dec}} = 10^{11} \text{ GeV} \left(\frac{f_a}{10^{12} \text{ GeV}}\right)^2 \left(\frac{0.1}{\alpha_s}\right)^3,$$  \hspace{1cm} (3)

the axinos cannot reach in the thermal equilibrium. Then axinos are generated through scatterings and heavy articles’ decay in the thermal plasma, the amount could be abundant enough for axino to be the dominant dark matter component \cite{14-16}. The abundance of thermally produced axinos depends on the reheating temperature for the KSVZ axion model \cite{26} \footnote{For DFSZ axion model \cite{29} the axino abundance is almost independent on the reheating temperature in the wide range \cite{30, 32}.}. The axino number density to entropy density ratio is estimated as \cite{15, 16, 27, 28, 29} \footnote{For non-thermally produced warm axino dark matter, see, e.g., Ref \cite{33}.}

$$Y_\tilde{a} = 2.0 \times 10^{-5} g_s^6 \log \left(\frac{1.108}{g_a}\right) \left(\frac{10^{11} \text{ GeV}}{f_a}\right)^2 \left(\frac{T_R}{10^6 \text{ GeV}}\right).$$  \hspace{1cm} (4)

With this, the relic density of non-relativistic axino at present is give by

$$\Omega_\tilde{a} h^2 = 0.28 \left(\frac{m_\tilde{a}}{10^{10} \text{ keV}}\right) \left(\frac{Y_\tilde{a}}{10^{-4}}\right).$$  \hspace{1cm} (5)

We can find that $O(1-10 \text{ keV})$ axino can be a natural candidate for warm dark matter when the reheating temperature is around $10^6 \sim 10^7 \text{ GeV}$ and Peccei-Quinn scale $f_a = 10^{11} \text{ GeV}$. Such thermally produced keV axino is a warm dark matter candidate \footnote{Such thermally produced keV axino is a warm dark matter candidate and may solve various problems at the small scale in cold dark matter model \cite{34, 35}. This range of reheating temperature is free from the gravitino problem \cite{36, 37}.} and may solve various problems at the small scale in cold dark matter model \cite{34, 35}. This range of reheating temperature is free from the gravitino problem \cite{36, 37}.
III. R-PARITY VIOLATION AND AXINO DECAY

We consider the bilinear type R-parity violation with the usual $\mu$-term superpotential in the minimal supersymmetric standard model

$$W_R = \epsilon_i \mu L_i H_u,$$

where $L_i$ and $H_u$ are chiral super fields of the lepton doublet and up-type Higgs doublet and $\epsilon_i$ parameterizes the size of the R-parity violation. By redefining the $L_i$ and $H_d$, we can eliminate the R-parity violating term in Eq. (6), then R-parity violating effect appears only in the scalar potential [38, 39],

$$V_R = m^2_{L_i H_d} \tilde{\nu}_i H_u^* + B_i \tilde{\nu}_i H_u + h.c.,$$

where the coefficients are $B_i \simeq -B \epsilon_i$ and $m^2_{L_i H_d} \simeq (m^2_{L_i} - m^2_{H_d}) \epsilon_i$. From this scalar potential, the sneutrinos obtain non-zero vacuum expectation values (VEVs)

$$\langle \tilde{\nu}_i \rangle = -\frac{m^2_{L_i H_d} \cos \beta + B_i \sin \beta}{m^2_{\tilde{\nu}_i}} v,$$

where $\tan \beta \equiv \langle H_u \rangle / \langle H_d \rangle$ and $v \equiv \sqrt{\langle H_u \rangle^2 + \langle H_d \rangle^2 / \sqrt{2}} \simeq 174$ GeV and $m_{\tilde{\nu}_i}$ is the sneutrino mass. Since the non-zero VEVs of sneutrinos induce mixings between leptons and gauginos, the neutrinos mix with neutralinos and can obtain mass at the tree level as [39]

$$m_\nu \simeq \frac{\mu^2 M_2^2 (M_1 g_2^2 + M_2 g_1^2) / g' \sum_i \xi_i^2}{(g^2 M_1 + g'^2 M_2) v^2 \mu \sin \beta \cos \beta - 2 M_1 M_2 \mu^2},$$

where $\xi_i$ parameterizes the R-parity breaking given by

$$\xi_i \simeq \frac{g' \langle \tilde{\nu}_i \rangle}{\sqrt{2} M_1}.$$

The upper bound of the neutrino mass $m_\nu \lesssim 1$ eV constrains the R-parity breaking parameters. For $\mathcal{O}(100$ GeV) gaugino mass, we have $\xi_i \lesssim 10^{-6}$. On the other hand, for light Bino $M_1 \ll M_2$, the constraint on $\xi_i$ is relaxed as

$$\sum_i \xi_i^2 \lesssim 10^{-7} g^2 \left( \frac{1 \text{ GeV}}{M_1} \right)^2.$$

Due to the R-parity violation, the stability of LSP is not guaranteed anymore [40, 42]. For bilinear R-parity breakings, the light axino decays dominantly into photon and neutrino
FIG. 1: The reheating temperature $T_R$ versus $f_a$ for given $\xi_i = 10^{-5}, 10^{-4}, 10^{-3}$ (Blue, Red, Green) respectively to explain X-ray line emission. The small value of $f_a < 5 \times 10^8$ GeV (cyan) is disallowed by the SN1987A. On the curved black line the thermally produced axino and non-thermally produced axion (misalignment) can give correct relic density for dark matter. The upper region of the black line is disallowed due to the overabundance of axino and axion dark matter.

and the decay rate is given by

$$\Gamma_{\tilde{a}} = \sum_i \Gamma_{\tilde{a} \rightarrow \gamma \nu_i} = \frac{C^2_{aY} \alpha^2_{em}}{128 \pi^3} \frac{m_{\tilde{a}}^3}{f_a^2} \sum_i \xi_i^2.$$  

(12)

Although axino can also decay to three neutrinos mediated by Z-boson, this mode is highly suppressed and negligible.

The X-ray emission line observed by the XMM-Newton can be explained with an appropriate lifetime and the relic abundance of axinos, if those satisfy the relation

$$\tau_{\tilde{a}} = \tau_{DM} \left( \frac{\Omega_{\tilde{a}} h^2}{0.1} \right),$$  

(13)

where $\tau_{DM}$ is given in Eq. (1). We note here that, even though the axinos are not the dominant component of dark matter, the enhanced decay rate can compensate to adjust the observed flux of X-ray line.

In Fig. 1 we show the parameter space of $T_R$ versus $f_a$ to explain the X-ray line emission for given R-parity violating parameters $\xi_i = 10^{-5}, 10^{-4}, 10^{-3}$ (Blue, Red, Green) respectively. Here the small value of $f_a < 5 \times 10^8$ GeV (cyan) is disallowed by the SN1987A and the upper
gray region is ruled out by the overabundance of the thermally produced axino and axions produced by the misalignment mechanism with an order unity misalignment angle \cite{43}.

In the white region and on the black strip, the axino decay can explain the X-ray line emission with proper values of $\xi \gtrsim 10^{-5}$. On the black strip, axino constitutes whole dark matter for $f_a < 10^{12}$ GeV, and axion contribution to dark matter is significant for $f_a \simeq 10^{12}$ GeV. For example, for $\xi_i = 10^{-4}$ in the region along the red stripe, the 3.5 keV X-ray line emission can be well explained and, on the crossing point with the black strip, axinos explain total dark matter in the Universe as well as the X-ray line emission. In the white region, the axino does not constitute all the component of dark matter the enhanced decay rate can properly adjust the required flux of X-ray. The rest of dark matter component must be compensated by another component of dark matter such as axions produced by another mechanism, e.g., the decay of heavier particles.

An interesting point to note is that the value of $\xi_i \gtrsim 10^{-5}$ implies light Bino $M_1 \lesssim 10$ GeV from Eq. (11) which is derived from the upper bound for neutrino mass.

IV. CONCLUSION

Axino is a good candidate for dark matter. When its mass is around 7 keV and R-parity is broken bilinearly, the axino decays into photon and neutrino. We studied this decaying axino warm dark matter in the light of the recent observation of X-ray line emission from the center of galaxy clusters and Andromeda galaxy observed by XMM-Newton. We find that the decaying axino can naturally explain the X-ray signal with/without additional component of dark matter. We note that the neutrino mass bound implies that the Bino mass is less than about 10 GeV.

Note added

As this work was being submitted, a paper \cite{44} appeared that also discusses decaying axino dark matter as a source of the X-ray line signal.
