Supporting Information

ABSTRACT: A blue reflective photonic polymer coating which can be patterned in full color, from blue to red, by printing with an aqueous calcium nitrate solution has been fabricated. Color change in the cholesteric liquid-crystalline polymer network over the entire visible spectrum is obtained by the use of nonreactive mesogen. The pattern in the coating is hidden in the blue color dry state and appears upon exposure to water or by exhaling breath onto it due to different degrees of swelling of the polymer network. The degree of swelling depends on the printed amount of calcium which acts as a cross-linker. The printed full color pattern can also be hidden simply by using a circular polarizer. The responsive full color camouflage polymers are interesting for various applications ranging from responsive house and automobile decor to anticounterfeit labels and data encryption.

KEYWORDS: full color, responsive, cholesteric liquid crystals, photonic pattern, inkjet printing

1. INTRODUCTION

Adaptive structural colors that arise due to the presence of periodic alteration of refractive indices are abundantly found in nature1 and perform various functions such as thermoregulation to control body temperature, signaling to communicate to other members of the same species, mimicry to warn predators, and camouflaging to hide from predators.2-4 Over the years, researchers have been working to generate adaptive full structural colors and camouflage in polymers. Such responsive photonic materials could be of interest in adaptive and camouflage textiles, smart coatings for house decors and automobiles, and anticounterfeit, for example.5 These full colored photonic materials6 generally consist of block copolymers, cholesteric liquid crystals, or colloidal crystals and they can be patterned by locally chemically modifying their responsive properties.5-16 Pattern fabrication using masks, however, severely limits production of diverse patterns, besides yielding patterns with only two colors. Although inkjet printing technology provides a viable solution for creating complex and diverse patterns, achieving full color camouflage in photonic-colored polymers remains a challenge.17-19

Cholesteric liquid-crystalline (CLC) or chiral nematic polymers,19-24 which are one-dimensional photonic materials, have captivated much attention because of the ease by which they can be fabricated into responsive materials. CLC polymers exhibit selective reflection of only one-handed circularly polarized light due to the presence of helical molecular organization with the wavelength of light reflected being directly proportional to length of the helical pitch. CLC polymers with responsive full color have not been explored. Until now, only chiral nematic mesoporous films with two colors have been reported.17-18 Previously, we have reported an optical calcium sensor based on a CLC polymer showing reflective colors ranging from green to blue.17 We now report on a printable blue-colored CLC polymer coating which can be patterned in full colors covering the visible spectrum from ∼480 to ∼640 nm with a single aqueous Ca(NO3)2 solution as the ink. The latent pattern reveals itself on exposure to water or by simply exhaling breath onto it (Scheme 1a). Arbitrary full color camouflage patterns can be printed in the photonic polymer which can be, in principle, reprogrammed by acid–base treatment.

2. EXPERIMENTAL DETAILS

2.1. Materials. RM257, RM105, and SCB were bought from Merck. 6OBA and 6OBAM were obtained from Synthon Chemicals. LC756 was bought from BASF. Irgacure 651 was obtained from CIBA. KOH pellets and Ca(NO3)2·4H2O were bought from Sigma-Aldrich. Tetrahydrofuran (THF) was obtained from Biosolve.

2.2. Functionalization of Glass Substrates. Methacrylate-functionalized and fluorinated alkylsilane-functionalized glass substrates were fabricated as reported previously.25 Glass slides were cleaned by sonicication (ethanol, 30 min) and then treated in a UV-ozone photoreactor (Ultra Violet Products, PR-100, 20 min) to activate the glass surfaces. It was followed by spin coating (3000 rpm, 45 s) 3-(trimethoxysilyl)propyl methacrylate solution (1 vol % solution in ethanol) and then curing (100 °C, 10 min) to get methacrylate-functionalized and fluorinated alkylsilane-functionalized glass substrates, respectively.

2.3. Preparation of Responsive CLC Polymer Coating. One gram of CLC mixture consisting of 17.9 wt % of RM257, 22.9 wt % of RM105, 18.0 wt % of each of 6OBA, 6OBAM, and SCB, 4.6 wt % of LC756, and 0.6 wt % of Irgacure 651 was dissolved in 2 mL of THF. Then 40 μL of this solution was cast on a methacrylate-functionalized 3 × 3 cm2 glass substrate. After the solvent was evaporated by heating

patterning with Ca2+(aq)

SCB

Ca2+ ions

“First, the nonreactive mesogen SCB was removed, leading to pitch shrinkage. After potassium salt polymer coating was obtained by treating with KOH, an aqueous solution of Ca2+ ions was used for patterning. In the wet state, areas with different amounts of Ca2+ ions swelled differently, giving rise to a full color pattern while staying indistinguishable from each other in a dry blue-colored state.

at 75 °C, a fluorinated alkylsilane-coated 3 × 3 cm² glass substrate was placed directly on top and cooled to room temperature with simultaneous shearing along one direction to obtain a greenish yellow film. It was then followed by photopolymerization by shining UV light (48 mW cm⁻² intensity in the range 320–390 nm) for 5 min after which the upper glass plate was removed to obtain the polymer coating. The polymer was first washed in THF and then treated with 1 M KOH to obtain the responsive potassium salt CLC polymer coating.

2.4. Characterization. Photopolymerization was done with an Omniruc series 2000 EXFO lamp. UV–visible spectra of the CLC polymer films were recorded in a PerkinElmer lambda 650 spectrophotometer. Ocean Optics UV–visible spectrophotometer HR2000+ mounted on a DM6000 M microscope from Leica Microsystems was used for measuring the transmission spectra of the photonic patterns. Height profile was determined with a Veeco Dektak 150 surface profiler. FT-IR spectra were measured on a Varian 670 FT-IR spectrometer with slide-on ATR (Ge). Inkjet printing was carried out on a Dimatix DMP 2800 (Dimatix-Fujifilm Inc., Santa Clara, USA) equipped with 10 pl cartridge (DMC-11610). Images and movie of the film were captured with a Sony Cyber-shot camera.

2.5. Patterning with Sponge in Polymer Coating. Features of dimension 10 × 2 × 1 mm³ were cut out from a kitchen sponge and were soaked each in different concentrations of Ca(NO₃)₂ solution, viz. 0.01, 0.1, 1, 5, 10, and 100 mM. The fully soaked sponges were then placed carefully on top of a potassium salt CLC polymer coating. After an hour, the sponges were removed. Some Ca(NO₃)₂ solution droplets which were left behind on the surface of the film were absorbed with dry tissue paper and then washed with running distilled water. A clean glass plate was placed on top to trap the water and keep the coating in wet condition for UV–vis measurements.

2.6. Patterning by Inkjet Printing in Polymer Coating. A 10 pl cartridge consisting of 12 nozzles with diameter 21.5 μm was used for printing. A 100 mM Ca(NO₃)₂ solution was used as the ink. Printing was carried out by using only 6 nozzles at room temperature with a voltage of 14.0 V and frequency 2.0 kHz using standard waveform. After the printing was over and a waiting period of an hour, the salts that had formed on the surface of the film were removed carefully with tissue paper and then washed with running distilled water. A clean glass plate was placed on top to trap the water and keep the coating in wet condition for UV–vis measurements.

3. RESULTS AND DISCUSSION

3.1. Fabrication of CLC Polymer Coating. The printable CLC polymer coating was fabricated from a monomer mixture (Scheme 1b) consisting of diacrylate (RM257) and mono-acrylate (RM105) mesogens. Hydrogen-bonded benzoic acid-functionalized polymerizable reactive mesogens (6OBA and 6OBAM) were used as ligands to bind to calcium ions. To induce a CLC phase, a right-handed chiral dopant (LC756), which also acts as a cross-linker, was added. Lastly, to enhance the response of the polymer coating to obtain a wide range of structural colors from blue to red, a removable, nonreactive mesogen (SCB) was used. The mixture also contained a photoinitiator (Irgacure 651, 0.6 wt %) to initiate the photopolymerization reaction. Shearing the CLC monomer mixture between methacrylate-functionalized and fluorinated alkylsilane-functionalized substrates resulted in planar alignment of the molecules which was frozen by photopolymerization using UV light. Removal of the top glass plate followed by washing away of the nonreactive mesogen SCB with THF revealed a blue-colored CLC polymer coating (λ = 450 nm) covalently bonded to the bottom plate (Figure S1a–c).

Treating the film with KOH solution resulted in rupture of hydrogen bonds and formation of potassium salt polymer. On drying, a 15 μm thick (Figure S1d) blue reflective (λ = 450 nm) hygroscopic polymer coating was obtained, which swelled and became red (λ = 630 nm) upon exposure to water due to an increase in the helical pitch. Drying led to pitch shrinkage and the coating returned to a blue color (λ = 450 nm), demonstrating a reversible color change covering almost the entire visible light spectrum.

3.2. Full Color Pattern Using Ca²⁺ as Cross-linking Agent. The color of the wet CLC polymer coating can be modified by Ca²⁺ ions which replaces K⁺ ions and bind to the benzoate moieties. Hence, photonic patterns can be created by locally introducing Ca²⁺ ions as cross-linkers. To determine the appropriate concentration of Ca(NO₃)₂ solutions required to achieve different colors in the visible spectrum, sponges were used in the form of stamps. Sponges of 10 × 2 × 1 mm³ were simply cut out from a kitchen sponge and soaked in different concentrations of Ca(NO₃)₂ solution ranging from 0.01 to 100 mM. The sponges were then placed carefully on top of the potassium salt photonic coating. A color change took place in less than a minute, indicating a rapid K⁺/Ca²⁺ ion exchange. UV–vis spectroscopy of the wet polymer coating showed only one reflection band for any concentration employed, suggesting that K⁺ and Ca²⁺ ions are uniformly distributed throughout the thickness of the film (Figure 1a). With concentrations 0.01 and
0.1 mM, the coating was found to reflect around 605 nm, that
is, $\Delta \lambda \approx 33$ nm blue-shifted with respect to wet potassium salt
coating, resulting in an orange color (Figure 1b). With
increasing concentration, the wavelength of light reflected
blue-shifted further due to a lower degree of swelling, causing a
decrease in pitch length. A concentration of 1 mM gave rise to
yellow color ( $\lambda \approx 578$ nm; $\Delta \lambda \approx 60$ nm) and 5 mM resulted in
a green reflection band ( $\lambda \approx 527$ nm; $\Delta \lambda \approx 81$ nm). With
higher concentration of 10 mM, the film became blue ( $\lambda \approx 484$
$\mu$m; $\Delta \lambda \approx 124$ nm). Increasing the concentration to 100 mM
did not cause any further color shift and the film remained blue,
suggesting all the K$^+$ ions have been replaced by Ca$^{2+}$ ions,
leading to a fully cross-linked polymer network with drastically
reduced degree of swelling. This data showed that the color of
the photonic polymer can be changed from red to blue ($\sim 480$
to $\sim 640$ nm) by varying the calcium concentration between 0.1
and 10 mM.

The use of sponge as a stamp to write full color patterns was
first investigated. The logo of the Eindhoven University of
Technology “TU/e”, which have the letters “T”, “U”, and “e” in
blue and the slash “/” in red was chosen as the full color
pattern. The background was selected to be green, and therefore a sponge (1 mm thick) soaked in 1 mM
concentration of Ca(NO$_3$)$_2$ was used as a stamp to generate
the green background. A small area was left untreated so that it
would develop into a red slash upon swelling with water. The
background consisted of both Ca$^{2+}$ and K$^+$ ions homogeneously
distributed while the slash consisted of K$^+$ ions only. Creating
the letters with sponges of the same thickness (1 mm) soaked
in 100 mM concentration of Ca(NO$_3$)$_2$ then led to local
exchange of the remaining K$^+$ ions with Ca$^{2+}$. Wetting the
patterned blue coating with water revealed the full color “TU/
e” image (Figure 2a). As designed, the background was green
($\lambda \approx 570$ nm) and letters were blue ( $\lambda \approx 483$ nm) while the
slash was red ( $\lambda \approx 636$ nm) (Figure 2b). Height profile
measurement of the wet coating revealed a decrease in
thickness in the region where the letters were written by 3.1
$\mu$m which translates to a 16.1% reduction (Figure 2c).

Figure 1. (a) Wavelength of light reflected by CLC potassium salt
polymer coating treated with different concentrations of Ca(NO$_3$)$_2$
solution. The red line represents the fitted curve. Error bars indicate
mean ± standard deviations for five measurements at different places
on the pattern. (b) Images of the CLC coatings patterned with kitchen
sponges soaked in different concentrations of Ca(NO$_3$)$_2$ solution.

Figure 2. (a) Image of a sponge-written “TU/e” logo that appeared in wet state on exposure to water or exhaled breath but remained hidden in the
dry state. (b) Wavelength of light reflected by the “TU/e” logo in wet and dry state. Error bar indicates mean ± standard deviations for five
measurements at different places on the pattern. (c) Height profile of the “TU/e” logo in wet state showed swelling for the slash and shrinkage
for the letters with respect to the green background and nearly flat surface in the dry state. (d) FT-IR spectra of the patterned CLC polymer coating.
Slash consisted of only K$^+$ ions. Background consisted of both K$^+$ and Ca$^{2+}$ ions. Letters consisted of only Ca$^{2+}$ ions. Polarized optical microscopy

corresponds well with the observed 15.3% decrease in the pitch length. On the other hand, the thickness increased by 2.3 μm in the region where the slash was written. This amounts to a 13% increase, corresponding fairly well with the observed 11.6% increase in pitch length on swelling. Polarized optical microscopy (POM) images showed a sharp border of the patterned area (Figure 2a,f), implying ions did not undergo lateral diffusion into the nonpatterned area, probably due to the anisotropy of the CLC material. The FT-IR spectra showed shifting of symmetric stretching peak of benzoate salt to higher frequency, from 1387 to 1394 cm⁻¹, while the asymmetric stretching peak shifted to lower frequency, from 1547 to 1537 cm⁻¹, confirming the formation of calcium benzoate dimers (Figure 2d) in the letter patterned areas.25,28,29 Drying the film resulted in disappearance of the pattern and the coating was totally blue (λ ≈ 448 nm) with a nearly flat surface profile (Figure 2b,c).

The trigger to reveal the hidden pattern is not limited to water. Water vapor present in exhaled breath (relative humidity ≈95%) was also enough to swell the coating to the same extent as that of water (Figure 2a). Response of the patterned coating was studied for ten cycles of exhaling breath (Figure S2a). It was found that repeated exposure to breath had negligible effect on the optical response of the coating. After the first cycle, the red slash became more orange but in the later cycles, the reflection wavelength stayed nearly the same (Figure S2b).

After the tenth cycle of exposure to exhaled breath, the color of the green background and blue letters remained nearly unchanged, implying that the response of the coating to breath is fully reversible. It should be noted that the colored photonic patterns can also be hidden using a circular polarizer. The pattern in the right-handed CLC polymer coating was visible through a right-handed circular polarizer while through a left-handed circular polarizer it was invisible and appeared completely dark (Figure 2g,h).

3.3. Arbitrary Full Color Patterning by Inkjet Printing.

To demonstrate that arbitrary full color high-resolution patterns could be easily fabricated in the photonic polymer coatings, inkjet printing was explored with 100 mM Ca(NO₃)₂ aqueous solution as a single ink. With a cartridge that ejects drops of 10 μL volume and 27 μm diameter, a line pattern of width 1 mm (Figure S3) was printed with spacing between the drops as 20 μm (1270 dpi). Swelling with water resulted in orange color pattern (λ ≈ 608 nm), slightly blue-shifted by Δλ ≈ 28 nm with respect to the nonprinted red area (λ ≈ 636 nm) (Figure S4). Printing a second layer on top of the first layer resulted in an increase in the amount of Ca²⁺ ions in the polymer network, leading to less swelling, and the pattern became yellowish green (λ ≈ 570 nm; Δλ ≈ 66 nm). On printing a third layer, the pattern became green (λ ≈ 532 nm; Δλ ≈ 104 nm) upon swelling. Printing additional layers led to further blue shifting of the reflection band until it became nearly constant around λ ≈ 489 nm (blue color; Δλ ≈ 147 nm) for 10 layers and more.

After having determined the number of layers required for obtaining a specific color, a flower with blue petals, green leaf and stem, and red pistils and background was chosen as an image for inkjet printing. With use of the cartridge with 100 mM Ca(NO₃)₂ ink solution and the same drop spacing of 20 μm (1270 dpi), the flower pattern was printed by varying the number of layers accordingly. The flower pattern stayed hidden in the dry state but in the wet state—either via exhaled breath or treatment with water—appeared in full color with high resolution (Figure 3, Movie S1). The POM images showed that the patterns were of uniform color, implying the drop spacing was optimum for obtaining uniform layers of the ink. The border of the pattern was sharp for the green leaf—stem (Figure S5a). However, the blue petals were surrounded by a ~170 μm broad green border (Figure S5b). As no lateral ion diffusion was observed in the case of sponge written patterns (vide supra), it is unlikely to occur in the inkjet-printed patterns. A possible explanation could be coalescence of printed ink drops at the border toward the bulk of the pattern causing a gradient of Ca²⁺ ions. The wavelength difference between the blue petals and the red background is large (Δλ ≈ 145 nm) while that between the green leaf—stem and the red background is relatively small (Δλ ≈ 87 nm); as a result, the gradient in Ca²⁺ concentration causing a gradient in color is more pronounced in the blue petals. Interestingly, the printed patterns could be erased by reprotonating the benzoate moieties by treating with an acid such as HNO₃ (Figure S6) revealing the possibility to erase and reprogram the camouflage patterns.25

For the making of green, yellow, and orange colors with more precise wavelengths, a different concentration of calcium nitrate could be used. For example, with use of a lower concentration 10 mM Ca(NO₃)₂ solution as the ink, patterns that reflect light of wavelength between 608 and 570 nm and 570 and 532 nm could also be obtained (Figure S4), signifying the versatility of Ca(NO₃)₂ solution in producing full color, covering almost the entire visible spectra from red to blue by simply varying the number of layers of the ink—100 or 10 mM concentrations. The photonic patterning by inkjet printing can be easily extended to printing any color pattern on any color background. For example, the “TU/e” logo could be printed with a green background and red slash and blue letters (Figure S7) to obtain a high-resolution pattern with sharp borders in the wet state.

4. CONCLUSIONS

We have fabricated a printable blue-colored CLC polymer coating that could be patterned with a single ink—calcium nitrate solution, in full colors covering the visible spectra from blue to red (~480 to ~640 nm). The patterns on the polymer functioned similarly to the naturally observed camouflage behavior by remaining hidden in dry environment and revealing itself in the presence of water or exhaled breath. The range of colors achievable could be tuned by simply changing the composition of the nonreactive mesogen. The responsive full color patterned photonic polymers open up many interesting applications of photonic materials in the direction of adaptive camouflage textiles, anticounterfeit labels, data encryptions as well as for aesthetic purposes including home decorations and automobile coatings.
