Impact of the SARS-CoV-2 epidemic on tuberculosis treatment outcome in Northern Italy

To the Editor:

We read with interest the letters by Tadolini et al. [1] and Stochino et al. [2] in a recent issue of the European Respiratory Journal, which summarise the first available evidence on tuberculosis (TB) and coronavirus disease 2019 (COVID-19) [3].

The COVID-19 pandemic poses dramatic challenges to the capacity of the global healthcare system. As of 25 June, 2020, Brescia Province, in Lombardy, reported 15 611 SARS-CoV-2 patients [4], accounting for 6.5% of all Italian cases, being one of the worst COVID-19 epicentres in Europe. The impact on healthcare delivery went far beyond the management of COVID-19 patients, as hospitals and health care facilities had to convert significant resources to its response.

Although overall reducing out-patient consultations, the Infectious and Tropical Diseases Department of the Spedali Civili of Brescia maintained all TB services unchanged and did not interrupt the cascade of TB care. We performed a retrospective, observational cohort analysis of the TB cascade of care among patients followed at the TB Clinic in Brescia in the period 1 March to 30 April, 2020 during the COVID-19 epidemic (study period) and compared them with those of March to April 2019 (control period). Data were censored at 30 June, 2020 and 2019, respectively. All patients who received a diagnosis of TB and who were receiving treatment for TB, either followed in the out-patients TB clinic or admitted to the wards, were included in the analysis. Demographic, clinical and treatment outcome information were retrieved from paper and electronic (NetCare version 1.05.12; Abeni Alba Software) clinical charts. Outcome indicators were the number of new TB diagnoses, TB treatment outcome, and adherence to the scheduled medical visits. Categorical variables were described using frequencies and percentages, and Chi-squared test or exact Fisher test were applied. Statistical analysis was performed using one tailed test considering significant p-values <0.05.

Overall, 65 patients entered TB care during the study period, compared to 76 in the control period. The diagnosis was based on microbiological criteria in 52 (80%) and 69 (79%) patients, respectively. There were no differences in age, gender, and proportion of foreign-born people during the two periods. In both periods there were three cases of multidrug-resistant TB, one case of extensively drug resistant TB (XDR-TB) and one pre-XDR TB. Of the three persons who died with TB during the COVID-19 period, one had a negative virologic test, and two were not tested.

Our study outcome indicators presented important statistical differences. First, during the study period six new TB diagnoses were made (9.2%), significantly fewer than the 15 new diagnoses (19.7%) in the control period (p=0.04). Second, the proportion of patients lost to follow-up was significantly higher in the study period compared to the control (10.8% versus 2.6%; p=0.03). Third, three deaths occurred during the study (4.6%), compared to none in the control period (p=0.04).

In detail, in the 2020 cohort seven of 65 patients (10.8%) patients were lost to follow-up, three (4.6%) had died, 10 had completed treatment (15.4%) and 45 (69.2%) were still engaged in care. In the control cohort, out of 76 patients, two patients were lost to follow-up (2.6%), none had died, 11 had completed treatment (14.5%) and 62 (81.5%) were still on TB treatment (figure 1).

It is important to recognise the impact of COVID-19 on TB care to mitigate its consequences. TB services have an urgent need to identify novel strategies to ensure the continuum of TB care at the time of the coronavirus pandemic. https://bit.ly/2OlKnwL

These data show that during the peak of COVID-19 epidemic our TB centre experienced a significant reduction of the number of TB diagnoses and an increase in the proportion of patients who were lost to follow-up or died, despite our efforts to keep TB services fully functional.

Although the potential negative impact of COVID-19 on TB services is fully recognised, data on TB treatment outcome are still limited. Some studies reported an increase in TB fatality rate associated with COVID-19 co-infection [1–3]. One study performed in Sierra Leone [5] showed trends in TB diagnosis similar to the one observed in Brescia. Besides, viral infections may have a detrimental impact on access to TB diagnosis and care, as recently summarised by ONG et al. [6]. Reasons for the reduction in TB diagnosis may include decreased attention to TB by healthcare systems, difficulties in accessing health services, lockdown measures, and fear of stigma and contagion. The same reasons may justify the increase in the proportion of cases who are lost to follow-up.

Our report has limitations, mainly the small sample size and the short observation period. However, this is the first report showing significant worsening in TB treatment outcome during the COVID-19 epidemic, supporting the hypothesis that the pandemic may seriously jeopardise TB diagnosis, care and management [7–9].

TB services have an urgent need to identify novel strategies to ensure the continuum of TB care at the time of the COVID-19 pandemic. The implementation of video observation therapy [10] may be a useful tool to ensure engagement to treatment during emergency periods. Furthermore, awareness campaigns targeting the whole health sector on the possible overlap of the clinical picture between COVID-19 and TB should be implemented to avoid diagnostic delays.

To conclude, it is important to recognise the impact of COVID-19 on TB care to mitigate its consequences. Essential health services should be maintained at their higher capacity level, even during exceptional events. Developing and strengthening policies to rapidly adapt TB control measures to the new challenge is a high and immediate priority.
