Paradoxical seizure exacerbation by anti-epileptic medication is a well-known clinical phenomenon in epilepsy, but the cellular mechanisms remain unclear. One possibility is enhanced network disinhibition by unintended suppression of inhibitory interneurons. We investigated this hypothesis in the stargazer mouse model of absence epilepsy, which bears a mutation in stargazin, an AMPA receptor trafficking protein. If AMPA signaling onto inhibitory GABAergic neurons is impaired, their activation by glutamate depends critically upon NMDA receptors. Indeed, we find that stargazer seizures are exacerbated by NMDA receptor blockade with CPP (3-[(R)-2-carboxypiperazin-4-yl]-prop-2-enyl-1-phosphonic acid) and MK-801, whereas other genetic absence epilepsy models are sensitive to these antagonists. To determine how an AMPA receptor trafficking defect could lead to paradoxical network activation, we analyzed stargazin and AMPA receptor localization and found that stargazin is detected exclusively in parvalbumin-positive (PV+) fast-spiking interneurons in somatosensory cortex, where it is co-expressed with the AMPA receptor subunit GluA4. PV+ cortical interneurons in stargazer show a near twofold decrease in the dendrite:soma GluA4 expression ratio compared to wild-type (WT) littermates. We explored the functional consequence of this trafficking defect on network excitability in neocortical slices. Both NMDA receptor antagonists suppressed 0 Mg2+-induced network discharges in WT but augmented bursting in stargazer cortex. Interneurons mediate this paradoxical response, since the difference between genotypes was masked by GABA receptor blockade.

Our findings provide a cellular locus for AMPA receptor-dependent signaling defects in stargazer cortex and define an interneuron-dependent mechanism for paradoxical seizure exacerbation in absence epilepsy.

INTRODUCTION

The ability of an anti-epileptic drug (AED) to aggravate seizures is an unwelcome clinical problem affecting a small percentage of individuals with epilepsy (Gayatri and Livingston, 2006). However, due to the underlying heterogeneity of human seizure disorders, no common predictive biomarker or mechanism linked to this malignant form of pharmacoresistance has been identified. Paradoxical seizure enhancement by drugs that ordinarily reduce membrane depolarization or excitatory synaptic transmission suggests an innate difference in intrinsic cellular excitability or functional connectivity mediating the aberrant neuronal synchronization. One possibility, a pre-existing defect in the strength of inhibitory interneurons, may offer a specific mechanism for this idiosyncratic response. For example, phenytoin aggravates myoclonic seizures in a severe form of infantile epilepsy, Dravet syndrome, arising from mutation of Scn1a (Guerrini, 2012). Recent analysis of haploinsufficient Scn1a mouse mutants found a decreased density of inward sodium current that preferentially impaired high frequency discharges in interneurons (Yu et al., 2006; Ogawa et al., 2007; Dutton et al., 2012). Further depression of their excitability by sodium channel blocking drugs such as phenytoin could synaptically disinhibit perisomatic cells, despite phenytoin’s simultaneous membrane suppressant effects on them. This example of malignant disinhibition arising from an inherently weakened interneuron population identifies a general mechanism for seizure exacerbation by otherwise potent anti-convulsant drugs.

In absence epilepsy, aggravation of seizures with anti-epileptic medication in some individuals is also well-described (Chaves and Sander, 2005; Thomas et al., 2006). In particular, GABAergic agents such as clonazepam, tiagabine, and vigabatrin that effectively terminate convulsive seizures typically provoke or prolong cortical spike-wave seizure patterns. An increase in tonic inhibition has been proposed (Crunelli et al., 2011) to explain the effects of these agents on thalamocortical oscillations in genetic models of epilepsy, however, the exact mechanism of seizure exacerbation with other anti-epileptic drugs lacking this property, such as lamotrigine, levetiracetam, and carbamazepine,
We identified a glutamate-related paradoxical response in the absence seizures (Pinault, 2003; Meeren et al., 2005;Beenhakker affect the thalamocortical loop implicated in the generation of phenotype, the AMPA receptor trafficking deficit should also clustering at synaptic and extrasynaptic sites in cerebellar granule cells (Chen et al., 2000). Although this explains the ataxic regulating protein (TARP) critical for AMPA subunit receptor regulatory protein (TARP) critical for AMPA subunit expression is unmasked in PV+ cells, and that lack of functional stargazin reduces dendritic GluA4 trafficking in these interneurons. We also find that NMDA receptors play a key role in limiting abnormal cortical synchronization in stargazer mice, since both competitive and non-competitive antagonists lead to parado ammonium concentrations greater than or equal to 2 × baseline voltage with a corresponding video-recorded behavioral arrest, was quantified by visual inspection. Total seconds of seizure activity, independent of seizure frequency or duration, were counted and divided by the baseline seizure duration at 30 min epochs to create a ratio specific to the 30 min baseline sampling period. Statistical differences were tested using a repeated measures ANOVA and Bonferroni post-tests to compare groups over time (Prism 5, version: 5.0d, GraphPad, CA, USA). Statistical significance was set at p < 0.05.

**IMMUNOCYTOCHEMISTRY**

All animal research was performed in accordance with Baylor College of Medicine Institutional Animal Care and Use Committee (IACUC) guidelines and regulations.

**IN VIVO VIDEO-EEG MONITORING**

Mice were anesthetized byAvertin and surgically implanted with bilateral silver wire electrodes (0.005” diameter) inserted into the subdural space over the parietal cortex bilaterally through cranial burr holes and attached to a microminiature connector cemented to the skull. Mice were allowed to recover for at least 48 h before analysis. EEG and behavioral activity in freely moving mice were analyzed using simultaneous video-EEG monitoring (Harmonie software version 6.1c, Stellate Systems). All EEG signals were filtered using a 0.3 Hz high-pass filter, 70 Hz low-pass filter, and 60 Hz notch filter. All in vivo experiments were initiated between 12 and 1 pm to prevent confounding diurnal variation. Mice were allowed to acclimate to the recording environment for 30 min, and video-EEG was then collected for a 30 min baseline sampling period, followed by intraperitoneal drug injection with either MK-801 (Sigma) or phosphate-buffered saline (PBS) and monitored for 3 h. Seizure activity, defined by spike and wave discharges with an amplitude greater than or equal to 2× baseline voltage with a corresponding video-recorded behavioral arrest, was quantified by visual inspection. Total seconds of seizure activity, independent of seizure frequency or duration, were counted and divided by the baseline seizure duration at 30 min epochs to create a ratio specific to the 30 min baseline sampling period. Statistical differences were tested using a repeated measures ANOVA and Bonferroni post-tests to compare groups over time (Prism 5, version: 5.0d, GraphPad, CA, USA). Statistical significance was set at p < 0.05.

**MATERIALS AND METHODS**

Mice

Experiments used adult homozygous stargazer mutants on a C57BL/6 background (stg/stg) and their wild-type (WT) littermate controls (+/+) . To selectively label PV+ cells in WT mice in vivo, we used a PV-Cre Ai9 (stop-floxed tdTomato) transgenic mouse line (Jackson Laboratory Stock #008069 and #003790). These mice have a 30% C57BL/6 background, with minimal contribution from the 129P3/J strain after four generations of cross-breeding, ultimately expressing Cre recombinase from the endogenous parvalbumin (Pvalb) locus (Madisen et al., 2010). However, due to the tight linkage of the stg and Pvalb loci on chromosome 15, we were unable to create a transgenic rat mutant expressing a Pvalb-driven reporter. Genotypes were confirmed by PCR of tail DNA with the following primers: GAG-CAAGCAGGTTCAGGC, TACTTCATCCGGCATCCCTC, and TGCGTTTCAGTGTGTTGGC, which produce a WT (360 bp) and mutant (155 bp) band (Burgess et al., 1997). All animal research was performed in accordance with Baylor College of Medicine Institutional Animal Care and Use Committee (IACUC) guidelines and regulations.

Stargazin is Selectively Expressed in PV+ Cells in Somatosensory Cortex
To explore the mechanism underlying paradoxical prolongation of
seizures following NMDA receptor blockade, we investigated the cellular localization of stargazin in neocortex. Fluorescence immuno
to a lesser degree, their soma (Figure 2, top). Of 71
PV+ interneurons identified through all layers of somatosensory
cortex over a region of 1.6 × 10−6 cubic millimeters in an adult
MT mouse, 68 (95.8%) expressed detectable stargazin immu
activity. There were no stargazin+ cells that were not also PV+.
No stargazin staining could be detected in pyramidal neuronal
processes in somatosensory cortex, unlike in the hippocampus, where staining in the apical dendrites of CA1 pyramidal neu
rons could be observed (Figure 3, top). In contrast, dendrites of neocortical PV+ cells in stargazer show no detectable stargazin
staining, and only faint staining in the soma (Figure 2, bottom).
FIGURE 1 | (A) Exacerbation of spontaneous spike-wave seizures following MK-801 in stargazer mice. Compared to ip saline, the total seizure duration is elevated by up to 448% 1 h post-injection with 0.5 mg/kg in stargazer mutants (*\(p < 0.05\), **\(p < 0.0001\)). At the same dose, seizures are entirely suppressed in tottering mice (†\(p < 0.01\), ††\(p < 0.0001\) compared to stargazer 0.5 mg/kg). A dose of 0.1 mg/kg was ineffective in stargazer mutant mice. Baseline seizure duration was obtained by summing burst durations over 30 min of acclimatized EEG recording. (B) Representative EEG traces at baseline and 1 h post-injection.

FIGURE 2 | Stargazin expression is restricted to PV\(^+\) interneurons in WT mouse somatosensory cortex (upper row). Somatodendritic stargazin immunoreactivity is lost in PV\(^+\) interneurons in stargazer mouse (lower row). Co-labeling of stargazin and parvalbumin antibodies shown in layer 2/3 at 63× magnification (scale = 10 μm).

To corroborate the PV\(^+\) co-localization, we also evaluated the cellular expression of stargazin using a floxed PV-Cre/Ai9 mouse expressing the red fluorescent protein tdTomato (TdT) in PV\(^+\) cells. In somatosensory cortex, 108 of 123 (86.4%) PV\(^+\) interneurons counted over a region of 1.9 × 10\(^{-2}\) cubic millimeters were immunopositive for stargazin. Again, no stargazin\(^+\) cells were detected that were not also TdT\(^+\). We noted six TdT\(^+\) cells in layers 5-6 which had a pyramidal morphology, as has been previously recognized in this PV-Cre line (Tanahira et al., 2009). None of these TdT\(^+\) pyramidal-shaped cells expressed stargazin, if excluded from the total, 108 of 119 (90.8%) TdT\(^+\) cells expressed stargazin.

To evaluate the extent of stargazin antibody specificity for PV\(^+\) interneurons throughout the cortex, other cortical regions were examined in an adult WT mouse expressing TdT in PV\(^+\) cells, sampling at least 6.4 × 10\(^{-3}\) cubic millimeters for each area. These regions showed somewhat greater heterogeneity of stargazin co-expression with parvalbumin. In retrosplenial cortex, 40 of 71 (56%) TdT-labeled cells expressed stargazin in soma and dendrites. Similarly, 42 of 76 (55%) in entorhinal cortex; 16 of 46 (35%) in frontal cortex; and 20 of 59 (34%) in occipital cortex expressed somato-dendritic stargazin in TdT\(^+\) cells. All of the 226 stargazin\(^+\) cells sampled in somatosensory, entorhinal, frontal, and occipital cortex were TdT\(^+\) and hence PV\(^+\) (Figure 3, middle and bottom). In contrast, in CA1, periform cortex, perirhinal cortex, and insular cortex, stargazin expression was found in both TdT-labeled and TdT-unlabeled cells (Figure 3, top).

STARGAZIN IS LINKED TO GluA4 EXPRESSION IN CORTICAL INTERNEURONS AND LOSS IMPAIRS TRAFFICKING

Since PV\(^+\) interneurons express the calcium-permeable AMPA receptor subunit GluA4 (Chang et al., 2010), we next investigated the cellular co-localization of stargazin and GluA4 proteins in somatosensory cortex. Stargazin expression was associated exclusively with GluA4 expression in the soma and proximal dendrites of PV\(^+\) cells in all layers (Figure 4). Sampling 2.5 × 10\(^{-2}\) cubic millimeters of somatosensory cortex in an adult WT mouse revealed no stargazin\(^+\) cells (0/96) that were not also GluA4\(^+\). Since loss of stargazin protein reduces membrane insertion and stabilization of AMPA receptors, we searched for evidence that GluA4 trafficking...
was also impaired in *stargazer* PV+ cortical interneurons. PV+ cells that expressed GluA4 were readily identified in *stargazer* somatosensory cortex, with clear staining of the soma; however, dendritic processes displayed visibly decreased staining for GluA4 in mutant PV+ cells compared to WT (Figure 5A). A total of 18 PV+ neurons from 4 stg/stg mice and 15 PV+ neurons from 3+/+ mice met all of the inclusion and exclusion criteria for dendritic densitometric analysis. In PV+ interneurons, there was a significant, near twofold decrease in the dendrite to soma ratio of GluA4 staining in mutant compared to WT controls (52%, \( p < 0.001 \), Figure 5B).

**NMDA RECEPTOR ANTAGONISTS CPP AND MK-801 AUGMENT STARGAZER NEOCORTEX EXCITABILITY IN VITRO**

In order to determine whether intracortical networks were sufficient to express the proepileptic effect of NMDA receptor antagonists, isolated cortical slices from WT and stargazer mice were perfused with 0 Mg2+ aCSF to generate synchronous epileptiform discharges, which are due to NMDA receptor activation (Traub et al., 1994). Extracellular field recordings of layer V neurons revealed no significant differences between the two genotypes in the frequency of extracellularly recorded bursts before drug exposure. Application of the competitive NMDA receptor antagonist CPP (10 μM) nearly completely abolished the 0 Mg2+ epileptiform discharges in WT slices (number of discharges/200 s, 0 Mg2+: 7.7 ± 2.4, \( n = 4 \); 10 μM CPP: 0.3 ± 0.3, \( n = 4 \), \( p < 0.001 \), Figures 6C). However, application of 10 μM CPP elevated network excitability in the neocortex of stargazer mice by 308% (number of discharges/200 s, 0 Mg2+: 6.0 ± 0.4, \( n = 4 \); 10 μM CPP: 18.5 ± 0.3, \( n = 4 \), \( p < 0.001 \), Figures 6C). In both genotypes, there was a nearly equivalent and significant decrease in mean duration of burst discharges by 93 and 87% in WT and stargazer mice, respectively (duration of discharges, WT: 0 Mg2+: 3.8 ± 0.8 s, \( n = 4 \); 10 μM CPP: 0.3 ± 0.3 s, \( n = 4 \), \( p < 0.001 \); stargazer: 0 Mg2+: 5.2 ± 0.3 s, \( n = 4 \); 10 μM CPP: 0.7 ± 0.3 s, \( n = 4 \), \( p < 0.001 \), Figure 6D).
Likewise, the non-competitive NMDA receptor antagonist MK-801 was perfused at varying concentrations on WT neocortical slices, where it nearly abolished 0 Mg²⁺-induced discharge activity at higher doses (Figure 7A). Bath application of MK-801 in 0 Mg²⁺ aCSF in WT slices decreased the mean discharge frequency by 49% at 1 μM, 75% at 3 μM, and 88% at 10 μM (number of discharges/200 s, 0 Mg²⁺: 10.2 ± 0.3 s, n = 4, p = 0.0273; 3 μM MK-801: 2.5 ± 0.5, n = 4, p = 0.0019; 10 μM MK-801: 1.3 ± 0.3, n = 4, p = 0.0007, Figure 7C). The discharge frequency of the 0 Mg²⁺-induced bursts never increased at any point during application of MK-801. In addition, application of MK-801 to WT slices decreased the mean discharge duration by 44% at 1 μM, 66% at 3 μM, and 89% at 10 μM (0 Mg²⁺: 4.5 ± 0.6 s, n = 4; 1 μM MK-801: 2.5 ± 1.1 s, n = 4, p > 0.05; 3 μM MK-801: 1.5 ± 0.3 s, n = 4, p = 0.0045; 10 μM MK-801: 0.5 ± 0.1 s, n = 4, p = 0.0005, Figure 7D). In contrast, application of 1, 3, and 10 μM MK-801 to stargazer slices did not block 0 Mg²⁺-induced bursting (Figure 7B), but rather, similar to the effects of CPP, increased the mean frequency of network discharges by 331% at 1 μM, 405% at 3 μM, and 451% at 10 μM (number of discharges/200 s, 0 Mg²⁺: 6.2 ± 1.4, n = 4; 1 μM MK-801: 20.4 ± 3.9, n = 4, p = 0.0139; 3 μM MK-801: 24.9 ± 4.3, n = 4, p = 0.0061; 10 μM MK-801: 27.8 ± 5.8, n = 4, p = 0.0108, Figure 7C). MK-801 decreased the mean duration of the discharges by 32% at 1 μM, 68% at 3 μM, and 85% at 10 μM (0 Mg²⁺: 3.4 ± 0.9 s, n = 4; 1 μM MK-801: 3.7 ± 1.1 s, n = 4, p > 0.05; 3 μM MK-801: 1.8 ± 1.3 s, n = 4, p = 0.0156; 10 μM MK-801: 0.8 ± 0.5 s, n = 4, p = 0.0023, Figure 7D). These data demonstrate that blockade of NMDA receptors with both competitive and non-competitive antagonists paradoxically increases neocortical excitability in stargazer cortex without the participation of subcortical circuitry.

**NMDA RECEPTOR-DEPENDENT CORTICAL HYPEREXCITABILITY IS MEDIATED BY INHIBITORY INTERNEURONS**

In order to examine the hypothesis that NMDA receptor antagonism mediates its paradoxical excitatory effect in stargazer neocortex through inhibitory interneurons, we blocked GABAergic transmission within the neocortical circuit with GABAA receptor antagonist and re-examined the effects of CPP on the 0 Mg²⁺-induced discharges in the fully disinhibited circuit. After co-application of 50 μM PTX, a GABAA receptor antagonist, and 100 μM CGP35348, a GABAB receptor antagonist, synchronous epileptiform discharges elicited in 0 Mg²⁺ aCSF increased in...
FIGURE 7 | Non-competitive NMDA receptor blockade with MK-801 also provokes paradoxical cortical network hyperexcitability in vitro. (A) In 0 Mg²⁺, discharges in WT cortex show a dose-dependent reduction in duration and frequency with application of MK-801. (B) In contrast, spontaneous 0 Mg²⁺-induced network bursting in stargazer cortical slices accelerates with increasing doses of MK-801. (C) Graphical representation of divergent response to increasing doses of MK-801 in WT and stargazer mice (*p < 0.05, **p < 0.005). In (D), there is a coordinate reduction in discharge duration with no significant difference between groups at each incremental concentration of MK-801.

frequency in both WT and stargazer mice (number of discharges/200 s in WT; 0 Mg²⁺: 8.2 ± 0.7, n = 4; 50 μM PTX and 100 μM CGP35348: 15.7 ± 2.9, n = 4, p = 0.0490; in stargazer; 0 Mg²⁺: 7.6 ± 0.8, n = 4; 50 μM PTX and 100 μM CGP35348: 16.4 ± 2.9, n = 4, p = 0.0392, Figure 8). However, perfusing 10 μM CPP in the presence of the two antagonists significantly reduced epileptiform activity, but to a similar extent in both genotypes (number of discharges/200 s, WT: 1.8 ± 0.4, n = 4; stargazer: 1.5 ± 0.3, n = 4, p < 0.001, Figure 8). These findings support the hypothesis that the paradoxical response to NMDA receptor antagonism in stargazer mice is mediated by cortical GABAergic interneurons.

DISCUSSION

Our findings pinpoint a likely synaptic mechanism for paradoxical spike-wave seizure exacerbation due to NMDA receptor antagonism, showing that it is present in stargazer, but not tottering mutant mice, and thus depends upon an interneuron-specific AMPA receptor dendritic trafficking abnormality. We show that expression of stargazin in adult mouse somatosensory cortex is confined to a singular population of fast-spiking, PV⁺ interneurons. These cells are primarily responsible for fast synaptotropic inhibition of neurons in both superficial and deep somatosensory cell layers (DeFelipe, 1997). This specificity was most pronounced in the somatosensory cortex, a region proposed to possess a low threshold for involvement in aberrant thalamocortical oscillations in rodent models (Polack et al., 2007). In stargazer mice, we identified a concomitant deficit in dendritic AMPA receptor trafficking in these interneurons. In vitro cortical network hyperexcitability, as evidenced by epileptiform bursting in a magnesium-free environment, was enhanced by NMDA receptor antagonists in stargazer somatosensory cortex but reduced in WT mice. The paradoxical excitability difference between epileptic and non-epileptic cortex in response to CPP was no longer evident when GABA receptors were completely blocked, indicating that hyperexcitability induced by NMDA receptor antagonism was mediated through interneurons.

PARADOXICAL SEIZURE EXACERBATION WITH MK-801 IS SPECIFIC TO STARGAZER MICE

In vivo administration of the NMDA receptor antagonist MK-801 markedly exacerbated seizures in stargazer mice but had an opposite effect in tottering mice, indicating that the paradoxical seizure aggravation is gene-linked, rather than a non-specific modulation of spike-wave seizures due to a confounding variable such as sedation. The excitatory effect of MK-801 was similar to that of CPP in stargazer mice (Nahm and Noebels, 1998), confirming that both competitive (CPP) and non-competitive NMDA (MK-801) receptor antagonism, rather than an off target effect of either drug, mediated the paradoxical response. MK-801 has also been shown to reduce spike-wave seizures in other rodent models of epilepsy, including the kindling model (Lojková et al., 2006) as well
as the WAG/Rij (Wistar Albino Glaxo from Rijswijk; Peeters et al., 1989; Citraro et al., 2006) and Genetic Absence Epilepsy Rats from Strasbourg (GAERS) models of absence epilepsy (Koerner et al., 1996), further supporting the specific association of the paradoxical response to NMDA receptor antagonism with the stargazer trafficking defect. In a prior study of stargazer mice, CPP exacerbation of spike wave activity was also clearly observed, although no significant difference in total seizure duration over the time period measured was reported (Aizawa et al., 1997). In that study, MK-801 at a dose of 0.5 mg/kg did not stimulate discharge activity, but did produce an “irregular pattern” of EEG epileptiform activation that could represent a prolonged period of absence status epilepticus as we have occasionally observed.

**STARGAZIN EXPRESSION IS REGIONAL AND LIMITED TO FAST-SPIKING INTERNEURONS IN SOMATOSENSORY CORTEX**

The specificity of stargazin expression in PV⁺ interneurons of the somatosensory cortex initially seemed at variance with previous findings that its phosphorylation is dependent on CaMKII (calcium/calmodulin-dependent protein kinase II), an enzyme which is restricted to excitatory neurons (Tomita et al., 2005; Tsui and Malenka, 2006; Opazo et al., 2010). However, these studies investigated stargazin function in the hippocampus, not in the cortex. The lack of stargazin expression in excitatory cells within somatosensory cortex, however, is consistent with the finding that phosphorylation of stargazin is dependent on CaMKII in dissociated hippocampal, but not cortical, cultured neurons (Inamura et al., 2006). In addition, a recent study found that stargazin is specifically expressed in interneurons in primary dissociated cortical cell cultures (Tao et al., 2013). Finally, the relative specificity for stargazin in inhibitory neurons rather than principal cells is a pattern that recurs in the cerebellum (Sternov and Leitch, 2012) and the thalamus (Menuz and Nicoll, 2008).

**COMPARTMENTAL AMPA TRAFFICKING DEFECT IN STARGAZER INTERNEURONS**

In the absence of functional stargazin, GluA4 trafficking may still be partially compensated by TARP redundancy mediated by other co-expressed gamma subunits (Menuz et al., 2008) as well as the recently described “TARPless” expression of calcium-permeable surface AMPA subunits at some synapses (Bats et al., 2012). Several other candidate interacting molecules for AMPAR trafficking have been proposed (Jackson and Nicoll, 2011). However, the relatively decreased dendrite to soma ratio of GluA4 expression in stargazer PV⁺ interneurons indicates that these potential compensatory mechanisms are incomplete and therefore define a specific vulnerability in this cellular subgroup. When specific antibodies for remaining gamma subunit family members become available, the exact cellular TARP expression profiles may clarify the cellular populations at risk for AMPA receptor impairment due to CaMKII subunit mutations.
The exclusive association of stargaze with GluA4+ neurons in the neocortex is phenotypically consistent with the recent finding that the Gria4 knockout mouse, which is devoid of GluA4 expression, also displays similar spike-wave seizures (Beyer et al., 2008; Paz et al., 2011). In both stargaze and Gria4 knockout mice, there is evidence for thalamic disinhibition due to a specific deficit of synaptic excitation at fast-spiking PV+ inhibitory neurons in the RTN (Barad et al., 2012). We therefore posit the presence of a similar functional defect of intracortical inhibition in this model due to a parallel deficit in the ability to excite fast-spiking PV+ interneurons in the somatosensory cortex.

**DOES DEFICIENT DENDRITIC GLUAA TRAFFICKING IMPAIR SYNAPTIC ACTIVATION OF INTERNEURONS IN STARGAZER CORTEX?**

The degree to which abnormal dendritic GluA4 distribution alters synaptic activation of interneurons and hence the efficiency of GABAergic transmission in parvalbumin reporter lines will be required to determine whether AMPA receptor mistrafficking reduces the strength of this input. One impediment to studying this lies in the coincidental proximity of the stargaze locus on chromosome 15 to the parvalbumin locus, separated by only 0.01 cM. This complicates the ability to identify these cells for physiological study in stargazer cortex using a simple genetic cross with parvalbumin promoter-driven reporters. Future studies using defined presynaptic glutamate activation and post hoc immunohistochemical identification of PV+ cells will be required to support this hypothesis. However, it is worth noting that the impairment of synaptic excitatory activation in hippocampal neurons depleted of the homologous TARP gamma-8 subunit, which constitutes the majority of TARP-mediated AMPA receptor surface expression in these cells, was small (Rouach et al., 2005).

**INTERNEURON-DEPENDENT NETWORK HYPEREXCITABILITY DUE TO NMDA RECEPTOR ANTAGONISM IN STARGAZER MICE**

Since we observed a reduction of dendritic AMPA receptor density in parvalbumin+ interneurons that are critical for feedforward inhibition, and because stargaze does not directly traffic NMDA receptors (Chen et al., 2000), we reasoned that the synaptic activation of these inhibitory neurons would largely depend on NMDA receptors. Enhanced NMDA receptor-mediated excitation of these inhibitory neurons would largely depend on the strength of cortical GABAergic inputs of the RTN has been reported in stargazer mice (Lacey et al., 2012), but the cortical node of the thalamocortical loop has not previously been investigated. This hypothesis was tested in a magnesium-free environment, which is a useful medium for evaluating the effect of anti-epileptic drugs (Aram and Lodge, 1998). Magnesium normally blocks the activation of NMDA receptors, and its omission from the intravenous bathing solution results in spontaneous burst discharges (Traub et al., 1994). Although 0 Mg2+-induced discharges do not have the same pathophysiology as in vivo spike and wave cortical discharges, they provide a reliable functional measure of cortical circuit excitability. Specifically, these discharges arise as a consequence of saturation of fast inhibition, which can be overcome with incremental NMDA receptor antagonism (Benardo, 1993). In solutions containing 0 Mg2+ and CPP, fast inhibition relies on AMPA receptor-mediated activation of interneurons (Ling and Benardo, 1995), which we predicted to be compromised in stargazer mice. This effect is consistent with our results showing a reduced spontaneous burst frequency with CPP and increasing doses of MK-801 in WT slices in a magnesium-free environment. Accordingly, both competitive and non-competitive blockade of NMDA receptors caused a paradoxical increase in discharges in stargazer cortex, consistent with a compromise of fast inhibition. The significant paradoxical increase in discharge rate supports the hypothesis that when AMPA receptor-mediated transmission is impaired, NMDA receptor antagonism in 0 Mg2+ not only fails to suppress seizure activity, but rather causes a further, dose-dependent reduction in inhibition. After pharmacologically removing GABAergic inhibitory inputs of the stargazer network with picrotxin and CGP53348, CPP application no longer produced a paradoxical excitability increase, indicating that the excitatory effect of CPP in stargazer mice is indeed mediated through inhibitory neurons within the isolated cortical network. Furthermore, GABA receptor antagonists applied independently of CPP significantly increased the frequency of the 0 Mg2+-induced discharges in neocortex of both stargazer and WT mice, which itself demonstrates that disinhibition can increase the frequency of 0 Mg2+ discharges in the cortex and is consistent with the interpretation that CPP mediates its excitation in the mutant by aberrant disinhibition.

Our findings in the isolated neocortex point to potential regional differences in the role of NMDA receptors and network oscillations at various nodes of the thalamocortical loop. Interestingly, in thalamic slices of stargazer mice bathed in 0.5 mM Mg2+, the application of 50 μM APV (6,7-diamino-3-phosphonooxalmurate), a competitive NMDA receptor antagonist like CPP, caused a significant decrease in evoked oscillations in thalamic nuclei, similar to WT slices (Lacey et al., 2012). Thus, the paradoxical effect of seizure exacerbation observed in vivo may primarily reside in the low threshold initiation zones in the somatosensory cortex. These data therefore support a more general hypothesis that a reduction in the strength of cortical inhibitory interneurons provides an attractive candidate mechanism for paradoxical seizure exacerbation by anti-epileptic drugs in some patients with absence epilepsy.
