Background: Obesity is reported to be associated with oxidative stress which can cause lipid peroxidation. However, the effects of gain in various weight-related anthropometric indices on lipid peroxidation remain unclear. We aimed to examine the cross-sectional and longitudinal associations between altered weight-related anthropometric indices and a marker of lipid peroxidation among urban adults in China.

Methods: A total of 3762 participants from the Wuhan-Zhuhai cohort were included in the present study, with a follow-up of 3 years. Six weight-related anthropometric indicators were measured and calculated, including waist circumference (WC), body mass index (BMI), waist-to-hip ratio (WHR), waist-to-height ratio (WHtR), a body shape index (ABSI), and body adiposity index (BAI). Individual urinary 8-iso-prostaglandin-F_{2α} (8-iso-PGF_{2α}) was determined via enzyme-linked immunosorbent assay to evaluate lipid peroxidation. We used generalized linear models to analyze the cross-sectional and longitudinal associations of weight-related anthropometric indices with a marker of lipid peroxidation and stratified analyses to estimate effect modification.

Results: We found significant relationships between WHR, WHtR, ABSI, and urinary 8-iso-PGF_{2α} at baseline. Each 1% increase in WHR, WHtR, and ABSI was significantly associated with a 0.007, 0.004, and 0.104 increase in log-transformed 8-iso-PGF_{2α} concentration, respectively (P<0.05). In longitudinal analysis, positive dose–response relationships were observed between gains in BMI, BAI, and increased 8-iso-PGF_{2α} after adjusting for potential confounders (P_trend<0.05). We also found that gender and smoking status modified the association of BMI gain and 8-iso-PGF_{2α} increment, and such an association was more obvious in female and non-smokers.

Conclusion: Our research implied that gain in anthropometric indices may result in a higher level of lipid peroxidation.

Keywords: weight-related anthropometric indices, lipid peroxidation, obesity, cohort study

Introduction

Obesity, a widespread pandemic leading to poor health nowadays, has attracted worldwide public attention. According to the recent World Health Organization report, more than one third of the adult population were categorized as overweight or obese globally, as were over 340 million children and adolescents.1 Several weight-related indices have been used to assess adiposity, among which body mass index (BMI) is the most widely used.2 Compared with BMI, waist circumference...
(WC) and waist-to-hip ratio (WHR) have advantages in reflecting body fat distribution and measuring central obesity that is linked to greater health risks.\(^3\)\(^4\) Additionally, other weight-related anthropometric indices were proposed to assess the accumulation of adipose, including waist-to-height ratio (WHR), a body shape index (ABSI), and body adiposity index (BAI). A review from Italian scholars reported that obesity may activate the innate immune system and promote oxidative stress.\(^5\)

Oxidative stress arises from a systemic disequilibrium of oxidation–antioxidation system due to overproductions of reactive oxygen species (ROS) or reactive nitrogen species (RNS), which could contribute to the initiation and progression of obesity-related diseases.\(^6\)\(^7\)\(^8\) Cell membranes and macromolecules may be damaged once this imbalance appears. Lipids, especially polyunsaturated fatty acids, are susceptible biomolecules that could be attacked by ROS, and generate peroxides ultimately. F2-isoprostanes (F2-isOP) are regarded as reliable markers among numerous lipid peroxides.\(^9\) The 8-iso-prostaglandin-F\(_{2\alpha}\) (8-iso-PGF\(_{2\alpha}\)), one well-known part of F2-isOP class, is usually detected in urine to reflect the level of lipid peroxidation.\(^10\) Some published literatures have suggested that elevated 8-iso-PGF\(_{2\alpha}\) was associated with obesity and fat accumulation.\(^11\)\(^12\)

To better achieve the early prevention of obesity-related diseases, further understanding on the relationship between adiposity and lipid peroxidation is necessary. Ohmori et al\(^13\) found that the levels of plasma 8-iso-PGF\(_{2\alpha}\) were significantly higher in the high BMI group. In the Framingham Heart Study, positive associations of BMI and WHR with urinary 8-iso-PGF\(_{2\alpha}\) were also documented.\(^14\) However, a cross-sectional study of 677 Japanese people showed that BMI has no significant relevance to urinary 8-iso-PGF\(_{2\alpha}\),\(^15\) which was inconsistent with the abovementioned findings. In addition to such controversial associations, independent effects of some new weight-related anthropometric parameters, such as ABSI and BAI, on urinary 8-iso-PGF\(_{2\alpha}\) remain largely unknown. And the study regarding the longitudinal associations of gain in weight-related anthropometric indices with urinary 8-iso-PGF\(_{2\alpha}\) change is limited. Accordingly, we aimed to investigate the effects of different weight-related anthropometric indices on urinary 8-iso-PGF\(_{2\alpha}\) levels, and further examine whether there are longitudinal associations between gain in weight-related anthropometric indices and altered urinary 8-iso-PGF\(_{2\alpha}\) levels among urban adults in China.

### Methods

#### Study Design and Population

Data used in this study were originated from the Wuhan-Zhuhai cohort, which is a community-based prospective cohort established between 2011 and 2012 as described previously.\(^16\) A total of 4812 participants aged 18–80 years who lived in the communities of Wuhan or Zhuhai city for more than 5 years were recruited at baseline survey. Participants were followed up every 3 years. In the current cross-sectional analysis, 3762 subjects were included after excluding those with a history of nephritis (n=43), missing information on 8-iso-PGF\(_{2\alpha}\) (n=926), and weight-related anthropometric indices (n=81) at baseline. The first follow-up survey was finished after 3 years, and a total of 2777 participants were recruited. We excluded participants who had missing data on weight-related anthropometric indices (n=1069) or failed to provide sufficient urine samples (n=322). Finally, 1386 participants were included in longitudinal analysis. Participants included and excluded showed no significant difference in basic characteristics including age and gender. The study has approval from the Ethics and Human Subject Committee of Tongji Medical College, Huazhong University of Science and Technology. Written informed consent was gained from residents before participation.

#### Covariate Data Collection

Covariates, including basic demographic information, lifestyle (smoking status, alcohol drinking, regular physical activity, cooking status), and history of disease, were collected through face-to-face interview by professionals. Smoking status covered ever smoking (current and former smoking) and never smoking. Drinking status covered ever drinking (current and former drinking) and never drinking. Physical activity was defined as exercising regularly at least two times per week and for more than 20 minutes each time within the past 6 months. Diet information (intake frequencies of grains, fruit, vegetables, meat, and smoked each day or week) were also collected.

#### Weight-Related Anthropometric Indices

Every participant underwent a physical examination that included anthropometric measurements, like weight, height, WC, and hip circumference (HC). All of them were accomplished through standardized protocol and technique. In brief, height and weight were measured via weighing scale and a ruler (RGZ-120 Jiangsu Suhong...
Medical measurement, participants stood upright and kept the heels, sacrum, and scapula in line. WC was done at the midpoint between the iliac crest and the lower costal margin, and HC at the maximum circumference of the buttocks. Other weight-related anthropometric indices, including BMI, WHR, WHtR, ABSI, and BAI, were calculated as follows: 17-19

\[
\begin{align*}
\text{BMI} &= \frac{\text{Weight(kg)}}{\text{Height}^2}\text{(m)}; \\
\text{WHR} &= \frac{\text{WC(cm)}}{\text{HC}(cm)}; \\
\text{WHtR} &= \frac{\text{WC(cm)}}{\text{Height}(cm)}; \\
\text{ABSI} &= \frac{\text{WC(m)}}{[\text{BMI}^{2/3}](\text{kg/m}^2)\text{Height}^{1/2}(\text{m})]; \\
\text{BAI} &= [\text{HC}(cm)/\text{Height}^{1.5}(m)]-18;
\end{align*}
\]

The gain in weight-related anthropometric indices were derived through the values of corresponding indicators in first follow-up minus the values at baseline. Overweight (≥24 kg/m²) is defined based on the BMI cut-off values presented by the Working Group on Obesity in China. 20

**Urinary 8-Iso-PGF2α Determination**

We collected spot morning urine to detect the levels of urinary 8-iso-PGF2α that have been widely accepted in large epidemiological investigations previously. The levels of urinary 8-iso-PGF2α were determined using a commercially available ELISA kit (Cayman Chemical, Ann Arbor, MI, USA) according to the manufacturer’s instruction. We controlled the intra- and inter-assay coefficients of variation below 5% and 10%, respectively. Urinary 8-iso-PGF2α concentration was calibrated by urinary creatinine (Cr) and finally expressed as ng/mmol Cr. Increased urinary 8-iso-PGF2α for each participant is the result of 8-iso-PGF2α in first follow-up minus the result at baseline.

**Statistical Analysis**

Urinary 8-iso-PGF2α concentration was log-transformed because of its right skewed distribution. Demographic characteristics across urinary 8-iso-PGF2α quartiles were compared using one-way ANOVA for continuous variables and Chi-square test for categorical variables.

The associations of weight-related and gain in weight-related anthropometric indices with urinary 8-iso-PGF2α and altered urinary 8-iso-PGF2α levels were evaluated using generalized linear models with adjustment for potential confounders, including age, gender, city, education, smoking status, alcohol drinking, physical activity, cooking meals at home, intake frequency of each kind of food (fruit, meat, smoked), history of hypertension, diabetes, and coronary heart disease.

Continuous models were used to calculate the regression coefficient and 95% confidence intervals of altered urinary 8-iso-PGF2α by each 1-unit increase in weight-related anthropometric indices, and categorical models to estimate regression coefficient of urinary 8-iso-PGF2α change across quartiles of different anthropometric indices gain. Furthermore, we assessed the relationships between altered urinary 8-iso-PGF2α and transition of overweight status during a 3-year period in two models. One was adjusted for single study factor, and another for all potential confounders. Statistical modification was performed by inputting an interaction term of interested weight-related anthropometric indices multiplied by the stratification covariates (age, gender, smoking status, alcohol consumption, and physical activity) in the generalized linear models, so as to clarify the modification effect of baseline demographic characteristics. All analyses were performed using SAS 9.4 (SAS Institute Inc., Cary, NC, USA).

**Results**

**Baseline Characteristics of Participants**

The 8-iso-PGF2α concentrations of all participants in urine samples ranged from 38.01-108.39 ng/mmol Cr, with a median value of 61.75 ng/mmol Cr. Baseline characteristics of the study population by quartiles of urinary 8-iso-PGF2α concentration are shown in Table 1. The mean age of 3762 subjects (1156 male, 30.73%) was 52.07±13.56 years old. Male individuals, cigarette smokers, alcohol drinkers, and those who ate vegetables, fruits, and smoked food frequently were more likely to have a higher urinary 8-iso-PGF2α level, whereas the results were the opposite among individuals who exercise regularly, eat more meat, and usually cook meals at home (P<0.05). As for weight-related anthropometric parameters, no differences were found across urinary 8-iso-PGF2α quartiles except for WHR and ABSI.

**Cross-Sectional Associations of Weight-Related Anthropometric Indices with Urinary 8-Iso-PGF2α**

The cross-sectional relationships between various weight-related anthropometric indices and urinary 8-iso-PGF2α in all participants and subgroups of non-overweight and overweight are shown in Table 2. With adjustment for

potential covariates, WHR, WHtR, and ABSI rather than BMI, WC, or BAII were significantly associated with 8-isopGF_2alpha in all participants (Table 2 and Figure 1). Each 1% increase in WHR, WHtR, and ABSI was significantly associated with a 0.007, 0.004, and 0.104 increase in log-transformed 8-isopGF_2alpha concentration, respectively (P<0.05). Additional subgroup analysis showed similar unimodal associations, and we found that the association of WHtR with 8-isopGF_2alpha is significant in the subgroup of non-overweight instead of overweight. The simple scatter plots with crude data between those relationships are shown in Supplementary Figure 1.

Longitudinal Associations of Gain in Weight-Related Anthropometric Indices with Altered Urinary 8-IsopGF_2alpha

As shown in Figure 2, the results of generalized linear models indicated positive dose–response relationships between increased 8-isopGF_2alpha and gain in BMI and BAII, after adjusting for potential confounders (all P<0.05). Consistent with categorical analyses, continuous analyses exhibited that average increase in 8-isopGF_2alpha was 2.65% (95% CI=0.32–4.98%) with per 1-unit gain in BAII (P<0.05). Change in other weight-related anthropometric indices (BMI, WC, WHR, WHtR, and
ABS1) were positively associated with an increase in 8-
iso-PGF$_{2\alpha}$ without statistical significance (Supplementary
Table 1). When contrasting with those overweight at baseline
but non-overweight at follow-up, females who were non-overweight at baseline but overweight at follow-up showed a 42.15% (95% CI=86.2–75.68%) increase in
urinary 8-iso-PGF$_{2\alpha}$ levels (Table 3).

Stratification analyses of selected characteristics are
presented in Table 4. Gender and smoking status were potential
effect modifiers of the association between BMI gain and altered
urinary 8-iso-PGF$_{2\alpha}$ levels ($P_{\text{for interaction}}$$<$0.05), and
no statistical significance was noted in other interaction
terms. The relationships between BMI, as well as BAI gain
and increased urinary 8-iso-PGF$_{2\alpha}$ were more remarkable
among females and nonsmokers. Thus, we then examined
such associations in subgroups of different genders and
smoking status. Among females or nonsmokers, but not
males or smokers, significant dose–response relationships
between anthropometric indices (BMI and BAI) gain and
increased urinary 8-iso-PGF$_{2\alpha}$ still existed. In addition,
individuals who cooked at home exhibited more pronounced
associations compared with those did not cook (Supplementary Tables 2 and 3).

**Discussion**

In this study, we explored the cross-sectional and lon-
titudinal associations of various weight-related anthropo-
metric indices with urinary 8-iso-PGF$_{2\alpha}$, a biomarker of
lipid peroxidation. We observed that urinary 8-iso-PGF$_{2\alpha}$
concentrations were increased along with elevated WHR,
WHtR, and ABS1 (an indicator reflecting body fat distri-
butions) among all participants in the cross-sectional
analysis. After follow-up of 3 years, we found significant
dose–response relationships between gain in BMI and
BAI and increased urinary 8-iso-PGF$_{2\alpha}$ in longitudinal
analysis. And such a relationship was more obvious in
females and non-smokers than in males and smokers.

Data from a Framingham Heart Study involving 1250
adults showed that subcutaneous adipose tissue and visceral
adipose tissue were related to higher urinary 8-iso-PGF$_{2\alpha}$
which indicated a direct cross-sectional association of vis-
ceral adiposity and oxidative stress.$^{21}$ In line with that, sub-
sequent studies implied both general adiposity (accessed by
BMI) and central adiposity (measured by WC and WHR)
were positively and similarly associated with lipid
peroxidation.$^{22-25}$ Besides, evidence from Japanese scholars
found that the relationship between urinary F$_2$-isoprostane
(a lipid peroxidation marker) excretion and BMI showed a
U-shaped curve with the lowest F$_2$-isoprostane level at BMI
23 among 15 subjects.$^{26}$ Indeed, our research also showed
positive relationships between weight-related anthropo-
metric indices (WHR, WHtR, ABS1) and urinary
8-iso-PGF$_{2\alpha}$ concentrations (a stable biomarker of lipid
peroxidation), which indicated central obesity may con-
tribute to lipid peroxidation by examining a large population
in China. However, with respect to BMI, we did not find its
effect on urinary 8-iso-PGF$_{2\alpha}$ at baseline, though this result
was in accordance with a Japanese study conducted on 677
healthy adults.$^{15}$ The possible explanations for the discrep-
ancy between our findings and previously published data
might be the differences in biological specimens and detec-
tion method of lipid peroxides. Blood specimens and mass
spectrometric methods were applied in some prior research.
While considering the short half-life of plasma F$_2$-isop and
large sample size.$^{15,27}$ immunoassays in urine may be a
more suitable method.
Figure 1  Associations between different weight-related anthropometric indices and urinary 8-iso-PGF$_{2\alpha}$ in baseline, adjusted for potential confounders (N=3762). Figures A to F represent the scatter plots of BMI (kg/m$^2$) (A), WC (cm) (B), WHR (%) (C), WHtR (%) (D), ABSI (m$^{1.6}$/kg$^{0.5}$) (E), BAI (0.01m$^{-0.5}$) (F), and urinary 8-iso-PGF$_{2\alpha}$ concentrations, respectively. All models were adjusted for age, gender (male/female), city (Wuhan/Zhuhai), education (middle school or below/high/University or beyond), smoking status (current or former smoker/never smoker), alcohol status (current or former drinker/never drinker), exercise (time for physical activity), intake frequency of each food type (fruit (≤4/>4 times/week), meat (≤4/>4 times/week), smoked food (≤1/>1 time/week), cooking (yes/no), history of hypertension (yes/no), diabetes (yes/no), coronary heart disease (yes/no).

Abbreviations: WC, waist circumference; BMI, body mass index; WHR, waist-to-hip ratio; WHtR, waist-to-height-ratio; BAI, body adiposity index; ABSI, a body shape index.
To our knowledge, our present results provided vital insight into altered urinary 8-iso-PGF₂α (a biomarker used to reflect the degree of lipid peroxidation) influenced by gain in weight-related anthropometric indices, which were largely unknown before. In the present study, as BMI or BAI levels keep increasing after 3 years, urinary 8-iso-PGF₂α concentrations were gradually increased. Furthermore, compared with the female who lost weight during 3-year follow-up, those with gained weight had increased urinary 8-iso-PGF₂α, suggesting that the levels of lipid peroxidation may strengthen with growing fat accumulation over time, especially in women. A study by Chae et al.²⁸ found that 122 overweight/obese participants exhibited decreased urinary 8-iso-PGF₂α after 3-year-long intervention involving daily 100-kcal calorie deficits. Il'yasova et al.²⁹ discovered that 2-year calorie restriction in healthy volunteers caused a statistical reduction in F₂-isop at both time points. Nevertheless, in the Insulin Resistance Atherosclerosis Study (IRAs) Cohort followed by 5 years, increased urinary F₂-isop levels predicted lower weight gain using the data from 299 individuals,³⁰ which showed incongruity with our results. The heterogeneity may be owing to the discrepancy of subject characteristics and sample size.

Figure 2 Associations between gain in weight-related anthropometric indices and change of urinary 8-iso-PGF₂α levels during 3-year follow-up (N=1386). All models were adjusted for age, gender (male/female), city (Wuhan/Zhuhai), education (middle school or below/high/university or beyond), smoking status (current or former smoker/never smoker), alcohol status (current or former drinker/never drinker), exercise (time for physical activity), intake frequency of each food type (fruit (≤4/>4 times/week), meat (≤4/>4 times/week), smoked (≤1/>1 times/week), cooking (yes/no), history of hypertension (yes/no), diabetes (yes/no), coronary heart disease (yes/no). *P_trend<0.05.

Notes: 1Single factor for generalized linear regression. 2Adjusted for age, gender (male/female), city (Wuhan/Zhuhai), education (middle school or below/high/university or beyond), smoking status (current or former smoker/never smoker), alcohol status (current or former drinker/never drinker), exercise (time for physical activity), intake frequency of each food type (fruit (≤4/>4 times/week), meat (≤4/>4 times/week), smoked food (≤4/>1 time/week)), cooking (yes/no), history of hypertension (yes/no), diabetes (yes/no), coronary heart disease (yes/no).

The explicit mechanism underlying the associations between weight-related anthropometric indices gain and higher level of lipid peroxidation over time remain not elucidated. The following pathways were likely to be involved. Enlarged white adipose tissue lead to the synthesis of various adipokines, which facilitate the generation of lipid peroxides in turn. Among adipokines, leptin serves as a crucial regulator for energy expenditure and food intake, and plays an important role in the formation of lipid peroxides; so as inflammatory cytokines from macrophages and monocytes, like TNF-α, IL-1, and IL-6. Experimental models have observed that the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase pathway (NOX) is another major source of ROS. NOX, particularly NOX4, shares the capacity to transfer electrons and convey various cellular signals. Marchesi et al found that vascular superoxide and NADPH oxidase activity was aroused in perivascular adipose tissue of New Zealand obese mice. In addition, susceptibility to lipid peroxidative injury is aggravating in obese individuals because of reduced antioxidant enzymes, such as superoxide dismutase (SOD), catalase (CAT), and glutathione peroxidase (GPX). Compared to those with a BMI of more than 40 kg/m², subjects with healthy BMI had significant higher SOD and GPX. And it has been proved that supplementation with antioxidants decreased systemic oxidative stress and plasma 8-iso-PGF2α concentrations among those of overweight or obese. Finally, visceral fat accumulation triggers increased lipid peroxidation through excess free fatty acids. As Randle et al identified that mitochondrial NADH/NAD⁺ ratio rose with high levels of fatty acid oxidation. Interestingly, the females were more likely to have stronger associations between anthropometric indices (BMI and BAI) gain and 8-iso-PGF2α increment, supporting the hypothesis that significant sex interactions were found between plasma 8-iso-PGF2α levels and most measures of adiposity. The prior literatures have indicated that a higher adipose tissue volume in women than men may be responsible for the gender differences. Another possible interpretation was menopausal status. Most researches have shown increased lipid peroxidation levels and decreased antioxidant status were discovered in postmenopausal women, and women over 50 years old took up a large percentage in our study. The concrete reasons for the gender difference in the relationships need to be investigated in the future.

There are several strengths in our study. First and foremost, we clarified the relationships of weight-related anthropometric indices and urinary 8-iso-PGF2α via both cross-sectional and longitudinal analyses in a relatively large population. Besides, several weight-related anthropometric indices which could evaluate the fat accumulation from different dimensions were applied to offer a better understanding of the associations. Third, we adjusted for potential confounders such as cigarette smoking and drinking. As for our limitations, participants involved in this study were followed with a short interval, as such, the indices of anthropometry and lipid peroxidation may not reflect a long-term change. Further studies are needed to explore their associations for a long period in a larger population. Another limitation is that information about dietary intake habits,
smoking, and drinking status were obtained through questionnaires, and possible bias in recall may exist. In addition, although all persons participating in physical examination were trained by professionals on the basis of the same standard, there is also the chance for bias in anthropometric measurement. Further studies are needed to confirm our results.

**Conclusions**

In summary, we found that WHR, WHtR, and ABSI are powerful predictors of lipid peroxidation that was reflected by urinary 8-iso-PGF$_2\alpha$ levels and associated closely with obesity-related health risks. Among females, pronounced dose-dependent relationships were reported between gain in BMI, BAI, and increased urinary 8-iso-PGF$_2\alpha$. The study highlights that BAI and BMI may also be suitable indicators of dynamic response to lipid peroxidation.

Diabetes, Metabolic Syndrome and Obesity: Targets and Therapy
Publish your work in this journal

Diabetes, Metabolic Syndrome and Obesity: Targets and Therapy is an international, peer-reviewed open-access journal committed to the rapid publication of the latest laboratory and clinical findings in the fields of diabetes, metabolic syndrome and obesity research. Original research, review, case reports, hypothesis formation, expert opinion and commentaries are all considered for publication. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit http://www.dovepress.com/testimonials.php to read real quotes from published authors.
