LETTER TO THE EDITOR

A “no-drift” runaway pile-up of pebbles in protoplanetary disks in which midplane turbulence increases with radius

Received 1 December 2020 / Accepted 22 December 2020

ABSTRACT

Context. A notable challenge of planet formation is to find a path to directly form planetesimals from small particles.

Aims. We aim to understand how drifting pebbles pile up in a protoplanetary disk with a nonuniform turbulence structure.

Methods. We consider a disk structure in which the midplane turbulence viscosity increases with the radius in protoplanetary disks, such as in the outer region of a dead zone. We perform 1D diffusion-advection simulations of pebbles that include back-reaction (the inertia) to the radial drift and the vertical and radial diffusions of pebbles for a given pebble-to-gas mass flux.

Results. We report a new mechanism, the “no-drift” runaway pile-up, that leads to a runaway accumulation of pebbles in disks, thus favoring the formation of planetesimals by streaming and/or gravitational instabilities. This occurs when pebbles drifting in from the outer disk and entering a dead zone experience a decrease in vertical turbulence. The scale height of the pebble subdisk then decreases, and, for small enough values of the turbulence in the dead zone and high values of the pebble-to-gas flux ratio, the back-reaction of pebbles on gas leads to a significant decrease in their drift velocity and thus their progressive accumulation. This occurs when the ratio of the flux of pebbles to that of the gas is large enough that the effect dominates over any Kelvin-Helmholtz shear instability. This process is independent of the existence of a pressure bump.

Key words. accretion, accretion disks – planets and satellites: formation – planet-disk interactions

1. Introduction

Forming planetesimals directly from small particles in an evolving protoplanetary disk is a major challenge in planet formation due to the “growth barrier” (Blum & Wurm 2000; Zsom et al. 2010) and the “drift barrier” (Whipple et al. 1977). Streaming instability (SI) may be a promising mechanism for forming planetesimals directly from pebbles, although it requires special conditions: the Stokes number \( r_s \geq 0.01 \) and a local elevated solid-to-gas ratio \((Z \equiv \rho_p/\rho_g \geq 1)\), where \( \rho_p \) and \( \rho_g \) are the spatial densities of pebbles and gas, respectively; Youdin et al. 2004; Youdin & Goodman 2005; Carrera et al. 2015). How, when, and whether such conditions are met in an evolving protoplanetary disk are still a matter of intense debate.

Different mechanisms have been proposed for planetesimal formation via the local enhancement of materials. They include the diffusive redistribution and recondensation of water vapor outside the snow line (e.g., Stevenson & Lunine 1988; Ciesla & Cuzzi 2006; Ros & Johansen 2013), and detailed numerical simulations have been performed (e.g., Drążkowska & Alibert 2017; Schoonenberg & Ormel 2017; Hyodo et al. 2019, 2021; Gárate et al. 2020). Other mechanisms include pile-ups at pressure maxima. These pressure maxima can be created by the planet’s gravity (e.g., Dipierro & Laibe 2017; Kanagawa et al. 2018), by a sharp change in the local magneto-rotational instability- (MRI-) driven turbulence structure at an evaporation front (e.g., Kretke & Lin 2007; Brauer et al. 2008), by a change in the gas accretion velocity at the inner (e.g., Chatterjee & Tan 2014; Ueda et al. 2019; Charnoz et al. 2019) and outer (e.g., Pinilla et al. 2016) edges of a dead zone, and/or by the change in the gas profile due to gas-pebble friction (back-reaction) combined with pebble growth (Gonzalez et al. 2017). However, a positive pressure gradient may not be likely because the non-magnetohydrodynamic (non-MHD) effects erase a clear transition between dead and active zones (e.g., Mori et al. 2017). The back-reaction of solids onto the gas would smooth out the bump (e.g., Taki et al. 2016; Kanagawa et al. 2018). Further studies are required to assess these likelihoods in an evolving disk.

Over the last few decades, MHD simulations have shown that a region where ionization is too low for the MRI to operate (i.e., a “dead zone”: Gammie 1996) might ubiquitously exist in the inner part of the disk midplane, and that only surface layers are magnetically active, supporting accretion (Fig. 1; Gressel et al. 2015; Simon et al. 2015; Bai & Stone 2013; Bai et al. 2016; Mori et al. 2017). The transition between active and dead zones might be smooth (i.e., the \( \alpha \)-parameter in the disk midplane \( \alpha_{\text{mid}} \) increases as a function of the distance to the star \( r \)), and \( \alpha_{\text{dead}} \equiv 10^{-3} - 10^{-3} \) is reported for the \( \alpha \)-parameter within a dead zone (e.g., Gressel et al. 2015; Simon et al. 2015; Mori et al. 2019). We note that the sound waves propagated from MRI-active surface layers (e.g., Okuzumi & Hirose 2011; Yang et al. 2018) and the vertical shear instability (VSI; e.g.,
Stoll & Kley 2016; Flock et al. 2020) could induce vertical mixing with an equivalent α for vertical diffusivity up to ≳ 10^{-3}, even within a dead zone. These results imply nonuniform disk turbulence structures.

In this Letter, we consider a toy model of a protoplanetary disk with a dead zone located at the inner region of the disk. We consider different α-parameters for the gas accretion and for the pebble motion. Including the effects of the back-reaction of pebbles onto gas, which slows the drift velocity of pebbles, we study how drifting pebbles within a dead zone pile up. We demonstrate that a runaway pile-up of pebbles occurs for a sufficiently large pebble-to-gas mass flux $F_{pg}$ when pebbles reach a critical low-level of turbulence; we call this the “no-drift” (ND) runaway pile-up (the summary of this mechanism is shown by a schematic illustration in Fig. 1). It is worth mentioning that the newly reported ND mechanism does not require the snow line or the pressure maxima.

In Sect. 2, we describe the disk models and settings of our 1D simulations that solve the diffusion-advection of drifting pebbles. In Sect. 3, we show the results of our 1D simulations as well as analytical arguments. In Sect. 4, we summarize this Letter.

2. Models and settings

2.1. Gas structure

Here, we adopt a toy model where the gas accretion toward the central star is characterized by a non-dimensional α-parameter $\alpha_{\text{acc}}$ (Fig. 1). Using the prescription of the classical α-accretion disk model (Shakura & Sunyaev 1973; Lynden-Bell & Pringle 1974), the surface density of the gas is given as

$$\Sigma_g = \frac{M_g}{3\pi\nu_{\text{acc}}} = \frac{M_g}{3\pi\rho_{\text{acc}}c_s^2\Omega_K^{1/2}},$$

where $M_g$ and $\nu_{\text{acc}} = \alpha_{\text{acc}}c_s^2\Omega_K$ are the gas mass accretion rate and the effective viscosity, respectively (c_s is the gas sound velocity and $\Omega_K$ is the Keplerian orbital frequency).

The gas rotates at sub-Keplerian speed. The degree of the deviation of the gas rotation frequency from that of Keplerian $\eta$ is given by

$$\eta \equiv \frac{\Omega_g - \Omega_K}{\Omega_K} = -\frac{1}{2} \frac{\partial \ln P_g}{\partial \ln r} \left( \frac{H_g}{r} \right)^2 = C_{\eta} \left( \frac{H_g}{r} \right)^2,$$

where $\Omega_g$, $P_g$, and $H_g$ are the gas orbital frequency, the gas pressure, and the gas scale height, respectively, and $C_{\eta}$ is defined as

$$C_{\eta} \equiv -\frac{1}{2} \frac{\partial \ln P_g}{\partial \ln r}.$$

which depends on the temperature profile (e.g., $C_{\eta} = 11/8$ for $T \propto r^{-1/2}$).

Using the α-disk prescription, the gas accretion velocity $v_{g}$ is written as

$$v_g = -\frac{3}{2} \frac{\nu_{\text{acc}}}{r} \left( \frac{1}{2} \frac{\partial \ln P_g}{\partial \ln r} \right)^{-1} = -\frac{3}{2} \nu_{\text{acc}} \eta \left( \frac{H_g}{r} \right)^2,$$

where a negative sign indicates accretion toward the central star.

2.2. Pebbles in the disk midplane

The radial drift velocity of pebbles, including the effects of gas-solid friction – drift back-reaction (hereafter Drift-BKR) – is given as (Ida & Guillot 2016; Schoonenberg & Ormel 2017; Hyodo et al. 2019)

$$v_p = -\frac{\Lambda}{1 + \Lambda^2 \tau_s^2} \left( 2r_c \Lambda \eta \nu_{\text{K}} - v_g \right),$$

where $\tau_s$ is the Stokes number of pebbles. $\Lambda \equiv \rho_p/(\rho_g + \rho_p) = 1/(1 + Z)$ characterizes the strength of the back-reaction due to the pile-up of pebbles, where $Z \equiv \rho_p/\rho_g$ is the midplane pebble-to-gas density ratio ($\rho_p = \Sigma_p/\sqrt{2\pi}H_g$ and $\rho_g = \Sigma_g/\sqrt{2\pi}H_p$, where $\Sigma_p$ and $H_p$ are the surface density and scale height of pebbles, respectively).

The disk midplane could be too weakly ionized for the MRI to operate (the dead zone with extremely weak turbulence; Gammie 1996). Thus, the disk midplane could have very different turbulence from that of gas accretion, which controls the disk surface density (i.e., $\alpha_{\text{acc}}$). In this Letter, we use an effective viscous parameter $\alpha_{\text{mid}}$ to characterize the radial and vertical diffusion processes of pebbles near the disk midplane (Fig. 1).

The scale height of pebbles characterizes the degree of pebble concentration in the disk midplane ($\rho_p \propto H_p^{-1}$). In the steady state, the scale height of pebbles is regulated by the vertical turbulent stirring (Dubrulle et al. 1995; Youdin & Lithwick 2007; Okuzumi et al. 2012; Hyodo et al. 2019) as

$$H_{p,\text{tur}} = \left( 1 + \frac{\tau_s}{\alpha_{\text{mid}} (1 + Z)^{-k}} \right)^{-1/2} H_g,$$

where a coefficient $K$ characterizes the strength of the back-reaction onto the diffusivity (Hyodo et al. 2019; Ida et al. 2021) and $K = 1$ is used (the choice of the $K$ value does not alter the conclusion – see Appendix A for the $K = 0$ case).
For a small \( \alpha_{\text{mid}} \) (i.e., for a small \( H_{p,\text{tur}} \)), a vertical shear Kelvin-Helmholtz (KH) instability prevents a further decrease in the pebble scale height. This minimum scale height, \( H_{p,\text{KH}} \), is (Hyodo et al. 2021)

\[
H_{p,\text{KH}} \approx R_{1/2} \left( \frac{Z^2}{(1 + Z)^2} C_{\eta} \alpha \right) \frac{H_{g}}{R} \leq R_{1/2} \left( \frac{Z^2}{(1 + Z)^2} \eta \right),
\]

which is valid for \( Z \leq 1 \), and \( Z \gg 1 \) indicates a gravitational collapse. Thus, the scale height of pebbles \( H_p \) is given as

\[
H_p = \max \left( H_{p,\text{tur}}, H_{p,\text{KH}} \right).
\]

2.3. Numerical settings

We performed 1D diffusion-advection simulations that included the back-reaction (the inertia) to radial drift of pebbles that slows the pebble drift velocity as pile-up proceeds (see details in Hyodo et al. 2019, 2021). The drift velocity of pebbles is given by Eq. (6), while the diffusivity is given as \( D_p = \alpha_{\text{mid}} C_{\eta} \alpha \Delta \left( \nabla \varphi \right)^2 \). We included back-reaction onto the diffusion of pebbles (with \( K = 1 \)). We assumed that pebbles drift outside the snow line, and the sublimation of pebbles was neglected (i.e., the dead zone exists beyond the snow line). The Stokes number of pebbles was set to be constant: \( \tau_s = 0.1 \) (Okuzumi et al. 2016; Ida & Guillot 2016). The disk midplane temperature was set to \( T(r) = 150 \text{ K} \times (r/3 \text{ au})^{-2} (\beta = 1/2) \). The surface density of the gas (molecular weight of \( \mu_g = 2.34 \)) is described by \( \Sigma_g = \frac{M_g}{3 \pi \nu_g} \), where \( \nu_g = \alpha_{\text{acc}} \nabla \Delta_k \). We used \( \alpha_{\text{acc}} = 10^{-2} \) and \( \frac{M_g}{M_0} = 10^{-8} M_0 \text{ yr}^{-1} \). These led to \( C_{\eta} = 11/8 \) for \( \Sigma_g \propto r^{-1} \) and \( T \propto r^{-1/2} \).

We considered a dead zone in the inner region of the disk midplane, and we used a non-dimensional turbulence parameter in the midplane \( \alpha_{\text{mid}} \), which differs from the one that characterizes gas accretion, \( \alpha_{\text{acc}} \) (Eq. (1)). The midplane \( \alpha_{\text{mid}} \) is modeled as

\[
\alpha_{\text{mid}}(r) = \alpha_{\text{dead}} + \frac{(\alpha_{\text{acc}} - \alpha_{\text{dead}})}{2} \left( \text{erf} \left( 3 + \frac{6(r-r^*)}{\Delta r_{\text{tra}}} \right) + 1 \right),
\]

where: \( \alpha_{\text{acc}} \) and \( \alpha_{\text{dead}} \) are those outside and inside a dead zone; \( r^* \) is the innermost radial distance, \( \alpha_{\text{mid}} = \alpha_{\text{acc}} \); and \( \Delta r_{\text{tra}} \) is the radial width of the transition from \( \alpha_{\text{mid}} = \alpha_{\text{acc}} \) to \( \alpha_{\text{mid}} = \alpha_{\text{dead}} \). As shown below, the ND mode occurs for an arbitrary choice of the dead zone structure, that is, irrespective of a sharp or a smooth change between the active and dead zones (i.e., an arbitrary choice of \( \alpha_{\text{dead}}, \alpha_{\text{acc}}, r^*, \) and \( \Delta r_{\text{tra}} \)), as long as it satisfies that \( \alpha_{\text{mid}} \) is smaller than a threshold value (Sect. 3.2.2).

At the beginning of the 1D simulations, we set the pebble-to-gas mass flux \( F_{p/g} \) at the outer boundary (\( r_{\text{out}} = 15 \text{ au} \)), and \( F_{p/g} \) at \( r_{\text{out}} \) was fixed throughout the simulations. We note that Elbakyan et al. (2020) performed a time-dependent simulation of disk formation to find a high \( F_{p/g} \) variation between \( O(10^{-4}) \) to \( O(1) \) in a single disk evolution (see also Ida et al. 2021).

3. Results

3.1. Numerical results

Figure 2 shows the results of our 1D simulations for different combinations of \( F_{p/g} \) and the midplane turbulence structures (i.e., different choices of \( \alpha_{\text{dead}}, r^* \), and \( \Delta r_{\text{tra}} \) in Eq. (10)) for the case of \( \alpha_{\text{acc}} = 10^{-2} \). The top panels show given turbulence structures (i.e., \( \alpha_{\text{mid}}(r)/\alpha_{\text{acc}} \)) and the bottom panels show the resultant midplane pebble-to-gas ratio in their spatial densities (i.e., \( p_g/p_{\ast} \)). The gray lines in the top panels are the analytically derived critical \( \alpha_{\text{mid}}/\alpha_{\text{acc}} \) below which a runaway pile-up of pebbles is expected to occur for a given \( F_{p/g} \) (Eq. (23) with \( F_{p/g} > F_{p/g,\ast} \)). The blue, green, and red lines in the bottom panels are those at \( t = 3 \times 10^3 \) yrs, \( t = 1 \times 10^3 \) yrs, and \( t = 3 \times 10^3 \) yrs from the beginning of the calculations, respectively. Panel a: system that reaches a steady-state, panels b–d: ND runaway pile-ups.

Fig. 2. \( \alpha_{\text{mid}}/\alpha_{\text{acc}} \) (top panels) and \( Z = p_g/p_{\ast} \) (bottom panels) as a function of the distance to a star in the 1D numerical simulations. Included are the cases where \( \alpha_{\text{acc}} = 10^{-2} \) and \( \tau_s = 0.1 \). From left to right: cases where \( (F_{p/g},\alpha_{\text{dead}},r^*,\Delta r_{\text{tra}}) = (0.11,10^{-4},9 \text{ au},5 \text{ au}), (0.17,10^{-4},9 \text{ au},5 \text{ au}) \) (0.47,10^{-4},9 \text{ au},5 \text{ au}), and (0.17,10^{-2},5 \text{ au},0.5 \text{ au}) \). The gray lines in the top panels represent the analytical critical \( \alpha_{\text{mid}}/\alpha_{\text{acc}} \) below which the ND runaway pile-up is expected to occur for a given \( F_{p/g} \) (Eq. (23) with \( F_{p/g} > F_{p/g,\ast} \)). The blue, green, and red lines in the bottom panels show the critical \( Z \) (i.e., \( Z_{\text{crit}} = 1 \)) above which the ND runaway pile-up occurs (Sect. 3.2).
same $\alpha_{\text{mid}}(r)/\alpha_{\text{acc}}$ as those in panels a and b, a runway pile-up of pebbles occurs more quickly and significantly (panel c in Fig. 2).

Comparing panels b and d in Fig. 2 (the same $F_{p/g}$, $\alpha_{\text{dead}}$, and $\alpha_{\text{acc}}$ but different shapes and locations of the transition between active and dead zones), 1D simulations demonstrate that a runway pile-up of pebbles occurs irrespective of the shape and location of the dead zone as long as $F_{p/g}$ is sufficiently large. This shows the robustness of this new mechanism of runaway pebble pile-up.

Numerical results show that when the change in the midplane turbulence on $r$ is smooth (i.e., $\alpha_{\text{mid}}$), the pile-up of pebbles efficiently propagates toward the outer region in the disk (compare panels b and d in Fig. 2). This indicates that, when the ND runway pile-up occurs at a given radial distance, a progressive pile-up of pebbles could occur even at a greater radial distance where the ND conditions are not met, leading to a global pile-up of pebbles for the SI to operate.

When $\alpha_{\text{acc}} \approx 10^{-3}$, 1D simulations only show a runaway pile-up of pebbles for a very large value of $F_{p/g}$ ($F_{p/g} \gtrsim 0.8$). This is because the surface density of the gas increases (Eq. (1)) for a smaller $\alpha_{\text{acc}}$, and $F_{p/g}$ correspondingly decreases.

3.2. Analytical arguments

3.2.1. Midplane concentration of pebbles

Below, we discuss the concentration of pebbles in the disk midplane considering Drift-BKR. Our arguments are made using the analytical equation presented below (Eq. (11)). We solve this equation using two distinct approaches: a direct numerical approach and an analytical approach with some approximation. In both ways, we identify a parameter space ($F_{p/g} = \alpha_{\text{acc}} - \alpha_{\text{mid}}$ space) where the ND runway pile-up of drifting pebbles could take place.

The concentration of pebbles at the midplane is written as

$$Z \equiv \frac{\rho_p}{\rho_g} = \frac{\Sigma_p}{\Sigma_g} = \frac{\nu_\rho}{\nu_p} h_{p/g} F_{p/g},$$

where $h_{p/g} \equiv H_p/H_g$ and $\nu_p$ are functions of $\Lambda(Z)$. We directly find a solution (i.e., solve for $Z$) for Eq. (11) for a given $F_{p/g}$ and $\alpha_{\text{mid}}$. The color contours in Fig. 3 show directly obtained $\rho_p/\rho_g$ and the red region is where no steady-state solution is found (i.e., the radial drift of pebbles is halted due to Drift-BKR). The dashed lines in Fig. 3 are analytically derived critical $F_{p/g,\text{crit}}$, above which no steady-state solution is found for $p_p/p_g$ (i.e., the ND runway pile-up). The analytical estimations reproduce the direct solutions well.

The $F_{p/g,\text{crit}}$ can be divided into two different regimes. In the first regime, $H_{p,\text{tur}} > H_{p,\text{KHL,max}}$, where $H_{p,\text{KHL,max}}$ is the maximum scale height of pebbles regulated by a KH instability. In this case, using Eqs. (5) and (6), the vertically averaged metallicity of pebbles is given as

$$Z_\Sigma \equiv \frac{\Sigma_p}{\Sigma_g} = \frac{F_{p/g} \times v_\rho}{v_p},$$

$$\approx \frac{F_{p/g} \times -\frac{1}{\alpha_{\text{acc}}} \eta \nu_c C_g^{-1}}{-\frac{A}{1 + \frac{1}{\alpha_{\text{acc}}} \eta \nu_c C_g^{-1}}},$$

$$\approx \frac{3 \rho_{\text{acc}} F_{p/g}}{4 \tau_\Sigma C_{\eta} \Lambda^2} = \frac{3 \rho_{\text{acc}} F_{p/g}}{4 \tau_\Sigma C_{\eta}} \left( 1 + h_{p/g} Z_\Sigma \right)^2,$$

where an approximation is made for $\alpha_{\text{acc}} \ll 1$, $Z \ll 1$, $\Lambda \approx 1$. Solving this equation gives

$$Z_\Sigma = \left( 1 - 2ab \right) \sqrt{\frac{1}{2ab} - 1},$$

where $a = 3 \rho_{\text{acc}} F_{p,\text{crit}} / 4 \tau_\Sigma C_{\eta}$ and $b = h_{p/g}^{-1}$. The $Z_\Sigma$ has a real solution when $1 - 4ab > 0$ and a critical $F_{p/g,\text{crit}}$ for the first regime is given as

$$F_{p/g,\text{crit}} \approx \frac{C_g}{3} \frac{\tau_\Sigma}{\alpha_{\text{acc}}} h_{p/g} = \frac{\left( \alpha_{\text{mid}} \tau_\Sigma \right)^{1/2}}{3 \alpha_{\text{acc}}} C_g,$$

$$\approx 0.15 \times \left( \frac{\alpha_{\text{acc}}}{10^{-3}} \right)^{-1} \left( \frac{\tau_\Sigma}{10^{-2}} \right)^{1/2} \left( \frac{\nu_\rho}{\nu_p} \right)^{1/2} \left( \frac{C_g}{11/8} \right),$$

where $h_{p/g} \approx \left( \tau_\Sigma / \left( \alpha_{\text{mid}} (1 + Z)^{-1} \right) \right)^{1/2} \approx \left( \tau_\Sigma / \alpha_{\text{mid}} \right)^{1/2}$ for $Z \ll 1$ and $\alpha_{\text{mid}} \ll 1 + \tau_\Sigma$ (Eq. (9)). The above criteria for $F_{p/g,\text{crit}}$ are independent of $r$, and thus the ND mechanism occurs irrespective of the position and shape of a dead zone as long as it satisfies its criteria (i.e., Eq. (16)). The diagonal dashed black line in Fig. 3 shows Eq. (16) and is in accordance with the direct solutions of Eq. (11) (color contours in Fig. 3). The critical $Z$ above
which the ND occurs, \( Z_{\text{crit}} \), is obtained by inserting Eq. (16) into Eq. (11), and \( Z_{\text{crit}} \sim 1 \) for the first regime. Analytical \( Z_{\text{crit}} = 1 \) agrees with the direct solution (color contours in Fig. 3). We note that because \( F_{p/g,\text{crit2}} \) is proportional to \( C_\eta \), it increases with a steeper \( \Sigma \) gradient at an outer boundary of a dead zone. However, the ND mode does not need a sharp boundary. If the boundary is very gradual, the change in \( C_\eta \) is negligible.

The second regime appears when a KH instability plays a role, which corresponds to \( H_{p,\text{crit}} < H_{p,\text{KH, max}} \). Thus, in this case, the scale height of pebbles is described by \( H_{p,\text{KH}} \), which is independent of \( \alpha_{\text{mid}} \). As \( \rho_p / \rho_g \) increases from zero, \( H_{p,\text{KH}} \) initially increases and reaches its maximum \( H_{p,\text{KH, max}} \) at \( Z = \rho_p / \rho_g = 1 / 2 \). As \( \rho_p / \rho_g \) further increases, \( H_{p,\text{KH}} \) decreases\(^1\). By smoothly connecting with the critical value of \( Z_{\text{crit}} \) in the first regime (i.e., \( Z_{\text{crit}} = 1 \) as well in the second regime, which agrees with the direct solution; see the color contours in Fig. 3), the critical \( F_{p/g} \) in the second regime \( F_{p/g,\text{crit2}} \) adopts \( H_{p,\text{KH}} \) (\( H_{p,\text{KH}} \) with \( Z = 1 \)), and \( Z_{\text{crit}} \) is given as

\[
Z_{\text{crit}} = \frac{\rho_g}{\rho_p} \left( \frac{\Sigma}{\Sigma_{\text{crit}}} \right)^{2} \left( \frac{H_{p,\text{KH}}}{h_{p,\text{KH}}} \right)^{2},
\]

\[
\simeq \frac{3 \Delta_{\text{acc}} \Sigma_{\text{crit}}}{4 \tau_{c} \Sigma H_{p,\text{KH}}^{2}} \left( \frac{Z_{\text{crit}}}{1} \right)^{-1},
\]

where \( h_{p,\text{KH}} \equiv H_{p,\text{KH}} / \Sigma_p \) and an approximation is made for \( \Delta_{\text{acc}} \ll \tau_{c} \ll 1 \) and \( \Lambda \gg 1 \). The \( \Delta_{\text{acc}} H_{p,\text{KH}}^{2} \) is \( \Lambda \) using \( H_{p,\text{KH}}^{2} \). Here, \( Z = 1 \) and \( \Delta_{\text{acc}} \equiv 1 / 2 \). Thus, \( F_{p/g,\text{crit2}} \) with \( C_\eta = 11 / 8 \) is given as

\[
F_{p/g,\text{crit2}} = \frac{C_\eta}{3} \left( \frac{\Delta_{\text{acc}}}{\alpha_{\text{acc}}} \right)^{-1} \left( \frac{\tau_{r}}{0.1} \right)^{1/2} \left( \frac{H_{p,\text{KH}}}{\rho_{g}} \right)^{3/2},
\]

\[
\simeq 0.06 \times \left( \frac{\Delta_{\text{acc}}}{\alpha_{\text{mid}}} \right)^{-1} \left( \frac{\tau_{r}}{0.1} \right)^{1/2} \left( \frac{H_{p,\text{KH}}}{\rho_{g}} \right)^{3/2},
\]

\[
\text{for } H_{p,\text{crit}} < H_{p,\text{KH, max}}
\]

which is independent of \( \alpha_{\text{mid}} \). We note that the above criterion for \( F_{p/g,\text{crit2}} \) has a very weak dependence on \( r \) through \( H_{p,\text{KH}} / r \). Equation (20) is plotted by a horizontal dashed black line in Fig. 3, and it shows a good consistency with the direct solution of Eq. (11). Including a KH instability (i.e., the second regime and Eq. (20)) prevents the scale height of pebbles from becoming increasingly smaller as \( \alpha_{\text{mid}} \) decreases, reducing the parameter range of the ND runaway pile-up\(^2\).

3.2.2. Criteria for the ND runaway pile-up

Summarizing the analytical arguments above, the scale height of pebbles decreases with decreasing \( \alpha_{\text{mid}} \) until a KH instability plays a role. As pebbles drift inward from the active to the dead zones in the disk midplane, \( \alpha_{\text{mid}} \) becomes smaller with decreasing distance to the star \( r \), while keeping a constant \( F_{p/g} \). This implies that the evolutionary path in the \( \alpha_{\text{mid}}/\alpha_{\text{acc}} - F_{p/g} \) space (Fig. 3) is a horizontal shift from right to left for a given fixed \( F_{p/g} \) as pebbles drift inward. Therefore, for the ND mode to take place, the following two conditions need to be met.

\(^1\) We note that \( H_{p,\text{KH}} \) is a mean square root of the vertical height of particles but not the truncated height of the distribution.

\(^2\) The vertical shear streaming instability (VSSI; Lin 2020) might affect the pebble scale height when the midplane diffusivity is very small. If the VSSI dominated over a KH instability for the scale height of pebbles, the ND mode would be regulated by the VSSI.

First, \( F_{p/g} \) needs to be sufficiently large to satisfy \( F_{p/g} \geq F_{p/g,\text{crit2}} \). As \( F_{p/g,\text{crit2}} = 1 / \alpha_{\text{acc}} \) (Eq. (20)), the ND mode is limited to relatively large \( F_{p/g} \) values for the \( \alpha_{\text{acc}} \approx 10^{-3} \) case (\( F_{p/g} \approx 0.8 \) at \( 5 \) au), while only moderate \( F_{p/g} \geq 0.08 \) is required in the case of \( \alpha_{\text{acc}} = 10^{-2} \).

Second, a sufficiently small \( \alpha_{\text{mid}} / \alpha_{\text{acc}} \) is required in order to have a sufficiently small scale height of pebbles. Rewriting Eq. (16) gives a critical \( \alpha_{\text{mid}} / \alpha_{\text{acc}} \) below which the ND occurs for a given \( F_{p/g} \) as

\[
\frac{\alpha_{\text{mid}}}{\alpha_{\text{acc}}} \equiv \left( \frac{3 \Delta_{\text{acc}}}{C_\eta} \right)^{2} \frac{\alpha_{\text{acc}}}{\alpha_{\text{mid}}} t_{s}^{-1},
\]

\[
\approx 4.76 \times 10^{-3} \left( \frac{F_{p/g}}{0.1} \right)^{2} \left( \frac{C_\eta}{11/8} \right)^{2} \left( \frac{\alpha_{\text{acc}}}{10^{-2}} \right) \left( \frac{\tau_{r}}{0.1} \right)^{-1},
\]

which is independent of \( r \). These two criteria are in very good accordance with the 1D simulations (See 3.1).

4. Conclusions

In this Letter, we studied how drifting pebbles pile up in a protoplanetary disk with a nonuniform turbulence structure, including the back-reaction of pebbles onto the gas that slows the drift velocity of pebbles as pile-up proceeds. We considered that gas accretion is regulated by an \( \alpha \)-parameter that is distinct from that of midplane turbulence. In the disk midplane, the turbulence strength can decrease with decreasing radial distance (e.g., the case where the inner region of the disk is an MRI-inactive dead-zone and the outer region is MRI-active). Thus, drifting pebbles are further concentrated in the midplane as the scale height decreases.

We demonstrated a new mechanism for a runaway pile-up of pebbles to occur for a moderate \( F_{p/g} \) when pebbles reach a critical level of low turbulence in the dead zone via a continuous slowing of their drift velocity due to the back-reaction (the ‘no-drift’ (ND) runaway pile-up). The ND runaway pile-up occurs irrespective of the shape of the dead zone. Our results imply that SI could also occur as a natural consequence of pebble drift in a protoplanetary disk with a dead zone.

The minimum scale height of pebbles in a dead zone is a critical parameter that characterizes the ND mode. Further studies that include detailed physical processes – such as a KH instability, VSI, vertical shear streaming instability, and the velocity fluctuation by the sound waves propagated from MRI-active surface layers – are required.

Appendix A: The case of $K=0$

Here, we show the case of $K=0$ where the diffusivity of pebbles is a fixed constant: $D_\rho = \rho_{\text{mid}}^2 \Omega_s^2 / (1 + \tau_s^2)$ (i.e., the back-reaction onto the diffusivity is neglected). Figure A.1 is the same as Fig. 2 but for the case of $K=0$.

As seen in the case of $K=1$ (Fig. 2), a runaway pile-up of pebbles within a dead zone occurs as long as $F_{p/g}$ meets the conditions discussed in Sect. 3.2.2 (the analytical arguments were made for $K=0$). Compared to the case of $K=1$, the radial width and the timescale of the pile-up are in general narrower and longer in the case of $K=0$ because the diffusivity is a constant for $K=0$, while it becomes smaller for $K=1$ as pile-up proceeds. These additional simulations with $K=0$ further show the robustness of the physical mechanism presented in this Letter and demonstrate that Drift-BKR, which slows the drift velocity of pebbles, is a fundamental ingredient for the ND mechanism.

Fig. A.1. Same as Fig. 2 but for the case of $K=0$.
