ABSTRACT

The incidence of colorectal cancer in young adults aged <50 years is increasing. In line with these recent trends, it is necessary to pay attention to young-onset colorectal adenoma, a precursor of colorectal cancer. Recent studies have reported that the prevalence of colorectal adenomas in young adults aged <50 years is not low. Moreover, it has been reported that the prevalence of advanced colorectal neoplasia (advanced adenoma or colorectal cancer) in young persons aged <50 years with clinical risk factors or a positive fecal immunochemical test result is not lower than that in average-risk older persons. In this review, I examined and summarized the prevalence and risk factors of colorectal neoplasia (colorectal adenoma or colorectal cancer) in young adults aged <50 years. Considering the results of previous studies, I proposed effective strategies for colorectal cancer screening using clinical risk factors and the fecal immunochemical test, and discussed post-polypectomy surveillance for this age group.

Keywords: Colorectal neoplasms; Young adults

INTRODUCTION

Colorectal cancer (CRC) is the third most common cancer and the second leading cause of cancer-related deaths worldwide [1]. Current guidelines recommend that people at an average risk for CRC start CRC screening at the age of 50 years [2]. Accordingly, the incidence of CRC in adults over the age of 50 has been decreasing over the past few decades. In contrast, the incidence of CRC in young adults under the age of 50 has increased recently. In South Korea, the incidence of CRC increased by 56%, 41%, 39%, and 30% in adults aged 30–34, 35–39, 40–44, and 45–49 years, respectively, between 1999 and 2015 [3]. A United States population-based study also demonstrated a significant increase in the incidence of CRC diagnosed in young adults [4]. Furthermore, based on current trends, the authors predict that by 2030, the incidence rate for colon and rectal cancers will increase by 28% and 46%, respectively for patients aged 35 to 49 years and by 90% and 124%, respectively for patients aged 20 to 34 years [4].
Given that adults under the age of 50 years comprise the majority of the economically active population, the increase in CRC in these young adults can exert a socioeconomic burden. Moreover, young adults with CRC have been reported to have more aggressive tumor characteristics than older adults [5]. Therefore, it is time to pay attention to CRC and colorectal adenomas, the precursors of CRC, that develop at a young age. In the present review, I aimed to discuss the prevalence and risk factors of colorectal neoplasia (CRN), including colorectal adenoma and CRC, in young adults aged <50 years, and propose effective strategies for CRC screening. I also discussed post-polypectomy surveillance for young adults aged <50 years by reviewing related studies.

PREVALENCE AND RISK FACTORS OF CRN IN YOUNG ADULTS AGED <50 YEARS

CRN was defined as CRC or any adenoma, while advanced colorectal neoplasia (ACRN) was defined as CRC or advanced adenoma [6]. Advanced adenoma was defined by the presence of at least one of the following features: ≥10 mm diameter, tubulovillous or villous structure, or high-grade dysplasia [6]. To date, several studies have examined the prevalence of CRN in asymptomatic adults aged <50 years; the results are summarized in Table 1. In South Korea, according to the Industrial Safety and Health Law, health screening examinations are required for all employees every year or every other year. As part of a welfare policy, companies often provide employees with comprehensive health screenings, including colonoscopy. Accordingly, although the guidelines recommend starting CRC screening at the age of 50, it is not uncommon for asymptomatic adults under the age of 50 years to undergo colonoscopy screening in Korea. For this reason, most studies on CRN in asymptomatic young adults aged <50 years have been conducted in Korea. Since age is the most powerful risk factor for CRN, it is natural that adults

http://pfmjournal.org
under 50 years of age have a relatively lower prevalence of CRN than those over 50 years of age. Although there have been differences between studies, the prevalence of CRN in adults aged 20–29, 30–39, and 40–49 years has been reported as 2.4%–9.4%, 8.0%–13.4%, and 3.5%–28.1%, respectively, and the prevalence of ACRN in the three age groups has been reported as 0.0%–0.6%, 0.4%–1.0%, and 1.7%–6.1%, respectively [7-18]. The prevalence of CRC in adults aged < 50 years is extremely low.

The risk factors for CRN in asymptomatic adults aged < 50 years reported in some studies are summarized in Table 2. The risk factors for CRN in adults under 50 years of age were similar to those in adults over 50 years of age. Most studies have reported that male sex, smoking, obesity, and factors involved in metabolic syndrome are risk factors for CRN or ACRN in young adults aged < 50 years [10-18].

Recently, two studies, including this one, have developed a model that predicts ACRN in adults under 50 years of age, beyond simply identifying risk factors for ACRN [19,20]. In this study, the predicted probability model for ACRN in adults aged 30 to 49 years included age, sex, body mass index (BMI), family history of CRC, and smoking habits, as follows: $Y_{ACRN} = -8.755 + 0.080 \times X_{\text{age}} - 0.055 \times X_{\text{male}} + 0.041 \times X_{\text{BMI}} + 0.200 \times X_{\text{family}_\text{history of CRC}} + 0.218 \times X_{\text{former_smoker}} + 0.644 \times X_{\text{current_smoker}}$ [19]. Another study proposed the Young Adult Colorectal Screening score for adults aged < 50 years, consisting of sex, age, alcohol, smoking, obesity, glucose metabolism abnormality, and family history of CRC, with scores ranging from 0 to 10 [20]. This score was classified into three tiers according to the risk of ACRN (0–4, low risk; 5–7, moderate risk; and 8–10, high risk) [20]. These models may be useful in selecting adults under 50 years of age who require colonoscopy.

### CRC Screening Strategies for Young Adults Aged <50 Years

The concern with screening colonoscopy performed before the age of 50 years is its low cost-effectiveness, because the risk of CRC or ACRN is relatively low in this population. Therefore, we pose the following questions. (1) Should young adults under the age of 50 be screened for CRC? (2) Which persons should be screened for CRC earlier? (3) Which CRC

| Study | Risk factors for CRN | Risk factors for ACRN |
|-------|----------------------|----------------------|
| Hong et al. (2010) [10] | 40–49 years: male sex, abdominal obesity, metabolic syndrome | 40–49 years: abdominal obesity, metabolic syndrome |
| Chung et al. (2010) [11] | 30–39 years: male sex, smoking | 40–49 years: male sex, smoking, family history of CRC |
| Chang et al. (2014) [12] | 30–39 years: male sex, smoking | 40–49 years: male sex, smoking, metabolic syndrome |
| Jung et al. (2015) [13] | 30–39 years: male sex, smoking, fatty liver, metabolic syndrome, obesity, elevated fasting blood glucose levels, elevated triglyceride levels | 30–39 years: smoking, fatty liver, elevated triglyceride levels |

screening modalities should be used for young adults aged <50 years? (4) At what age should CRC screening start in young adults aged <50 years? To answer these questions, I have conducted several studies, and in the present review, I discuss related studies, including my own studies.

Clinical risk stratification can be useful as a CRC screening strategy for adults under 50 years of age. A Taiwanese study showed that men aged 40 to 49 years with concurrent metabolic syndrome and smoking had a significantly higher prevalence of ACRN than average-risk women aged 50 to 59 years (6.2% vs. 2.1%, P = 0.03), and the number of colonoscopies needed to detect one ACRN was 14.6 versus 47.4, for those respective age groups [12]. These findings may justify a male smoker with metabolic syndrome commencing screening colonoscopy earlier, that is, commencing screening colonoscopy at age 40. One study revealed that the number needed to screen (NNS) to identify one adult patient with ACRN aged 30 to 44 years old with multiple clinical risk factors (including male sex, smoking, metabolic syndrome, and obesity) was higher than that in ≥ 50-year-old women, whereas NNS for those 45 to 49 years old with the same risk factors was lower than that for ≥ 50-year-old women (NNS 16.9–22.9 vs. 26.4) [21]. These findings suggest that individuals with clinical risk factors may benefit from commencing screening colonoscopy at 45 years. This is supported by another study that examined the age-specific prevalence of ACRN based on clinical risk factors and fecal immunochemical test (FIT) results in individuals without a family history of CRC [22]. In this study, 1-, 2-, and 1-point scores were assigned to male sex, smoking history, and obesity, respectively, based on the regression coefficient [22]. Even though individuals may have no family history of CRC, the prevalence of ACRN in individuals with ≥ 2 points (for example, smokers or obese men) rapidly increased as age increased to mid-40s, suggesting that early colonoscopy can be recommended in this age group [22].

In addition to clinical risk stratification, FIT may be a good choice for CRC screening in a young population because of its advantages of non-invasiveness and low cost. Some prior studies support this [23-25]. One study demonstrated that the diagnostic performance of FIT for ACRN in a young population (<50 years) was not inferior to that in the current screening-age population (≥ 50 years). In this study, there were no significant differences in the sensitivity (22.1%, 17.2%, and 22.0%; P = 0.435) and specificity (97.2%, 97.4%, and 96.9%; P = 0.344) of FIT for detecting ACRN between the 30–39, 40–49, and ≥ 50 age groups, respectively [23]. Rather, the 30 to 39 age group had a significantly higher accuracy of FIT for ACRN (96.7%, P < 0.001) than the 40 to 49 and ≥ 50 age groups (95.9% and 93.8%, respectively) [23]. These results support the assessment that FIT may be a good test for detecting ACRN in a young population. However, the age at which young adults aged <50 years benefit from commencing FIT remains unclear. To determine the age for commencing CRC screening via FIT, another study assessed the risk of ACRN in individuals aged 30–34, 35–39, 40–44, and 45–49 years based on the results of FIT, compared with that of average-risk individuals aged 50 to 59 years [24]. As a result, FIT-positive individuals aged 35–39, 40–44, and 45–49 years had a higher risk of ACRN than average-risk individuals aged 50 to 59 years (9.7%, 7.7%, 14.6% vs. 3.8%; P = 0.001, P = 0.014, and P < 0.001, respectively), whereas FIT-positive individuals aged 30 to 34 years did not (2.9% vs. 3.8%, P = 0.566) [24]. These findings suggest that FIT-positive individuals aged 35 to 49 years may benefit from screening colonoscopy, thus justifying the possibility of commencing FIT from the age of 35 years. A Taiwanese study also proposed that screening with FIT could be extended to persons aged 40 to 49 years [25]. In this study, individuals aged 40 to 49 years with positive FIT had a three-times higher CRC risk than those aged 50 to 59 years without FIT, with NNS at 42 and 135, respectively [25]. Regarding CRC incidence rate, the hazard ratio (HR) for those aged 40–44 or 45–49 years with a positive FIT was 2.3 and 5.7 times higher than the HR for those aged 50–54 years, respectively [25]. In line with these findings, the guideline updated from the American Cancer Society in 2018 recommends starting regular CRC screenings at the age of 45 years [26].

A combination of clinical risk stratification and FIT may be a more effective strategy for CRC screening in young populations. In a recent study, I proposed a two-step evaluation based on clinical risk stratification, followed by FIT [27]. In this study, Asia-Pacific Colorectal Screening (APCS) scores were used. Based on the APCS scoring system, 1-, 2-, and 1-point scores were assigned to male sex, family history of CRC in a first-degree relative (FDR), and current or past smoking history, respectively [28]. FIT-positive individuals 40 to 49 years old with an APCS ≥ 2 have a higher risk of ACRN than individuals aged ≥ 50 years with an APCS ≥ 4 (13.4% vs. 5.8%, P < 0.001) [27]. Based on these results, a two-step strategy to determine whether early colonoscopy is warranted, follows. Individuals aged 40 to 49 years are first assessed by APCS. If they have an APCS score ≥ 2, they undergo FIT. Those with positive FIT results undergo early colonoscopy [27].

A FIT result is used clinically as a binary outcome (“negative”
or “positive”) to identify individuals above a predetermined cut-off concentration. However, FIT allows for the quantification of fecal hemoglobin (f-Hb) levels. Several studies have demonstrated that higher f-Hb concentrations are significantly associated with a greater risk of ACRN [29-32]. Furthermore, some studies have suggested that risk stratification for ACRN combining f-Hb concentration and clinical risk factors can provide better diagnostic accuracy than using FIT binary results alone [29,30]. The use of quantitative f-Hb concentration in combination with clinical risk factors may be useful for prioritizing individuals who require early colonoscopy.

**PROPOSED CRC SCREENING ALGORITHM USING CLINICAL RISK STRATIFICATION AND FIT FOR YOUNG ADULTS AGED <50 YEARS**

Considering the results of previous studies and my studies, I propose a CRC screening algorithm using clinical risk stratification and FIT for young adults aged < 50 years (Fig. 1). Clinical risk stratification is the most easily available modality in a clinical setting. Smoking history can be easily checked by listening to a past history, and obesity can be easily confirmed by measuring the patient’s height and weight. Metabolic syndrome can also be confirmed by medical history. Therefore, clinical risk stratification using risk factors for CRN was first used in the proposed CRC screening algorithm. Clinical risk factors for CRN include male sex, smoking, obesity, metabolic syndrome, and family history of CRC in an FDR.

The proposed algorithm is described in detail as follows.

**POST-POLYPECTOMY SURVEILLANCE FOR YOUNG ADULTS AGED <50 YEARS**

Since the target age for screening colonoscopy is over 50 years, the current guidelines for surveillance after polypectomy are tailored to persons ≥ 50 years old. Currently, there are no specific recommendations for surveillance after removal of colorectal adenomas in young patients < 50 years of age. It has been reported that there are marked differences in recommendations for surveillance for young patients with colorectal adenomas among clinicians [33]. These differences are not surprising given that there are no specific recommendations for the surveillance of young-onset colorectal adenomas. The guidelines recommend a repeat colonoscopy in 5 to 10 years for patients with low-risk adenomas (1–2 non-advanced adenomas, < 10 mm in size) and 3 years for patients with high-risk adenomas (advanced adenoma or ≥ 3 adenomas) [6,34]. These low- and high-risk groups were stratified based on the probability of developing metachro-
nous ACRN. However, these guidelines are based on the findings of studies conducted in patients aged ≥ 50 years. It remains unclear whether it is appropriate to apply these guidelines equally to young adults aged < 50 years.

To date, several studies have investigated the risk of metachronous ACRN in patients aged < 50 years with colorectal adenoma removed. In a pooled analysis of eight prospective studies including 9,167 patients with previously resected colorectal adenomas, patients aged < 40 years (adjusted odds ratio [aOR], 0.41; 95% confidence interval [CI], 0.17 to 0.94) and those aged 40 to 49 years (aOR, 0.67; 95% CI, 0.48 to 0.93) had a lower risk of metachronous ACRN compared to those aged 50 to 59 years [35]. My previous study involving 10,014 patients also demonstrated that after high-risk adenoma removal, the 3-year risk of metachronous ACRN in patients aged 30–39 and 40–49 years was lower than in those aged ≥ 50 years (1.9% and 3.6% vs. 8.1%; P < 0.001 and P = 0.008, respectively). After low-risk adenoma removal, the 5-year risk of metachronous ACRN in those aged 30–39 and 40–49 years was lower than in those aged ≥ 50 years (2.8% and 3.3% vs. 5.9%; P = 0.010 and P = 0.031, respectively) [36]. These two studies suggest that the post-polypectomy surveillance colonoscopy interval may be extended for patients under 50 years of age than in patients over 50 years of age. This suggestion should be limited to young patients without genetic syndromes, such as familial adenomatous polyposis or hereditary nonpolyposis CRC.

However, some studies have shown inconsistent results with the two studies mentioned above. In a Korean multicenter cohort study, the risk of metachronous ACRN did not differ between patients aged 20 to 49 years and those aged 50 to 54 years [37]. More specifically, in the baseline high-risk adenoma group (n = 840), the 3-year risk of metachronous ACRN was 10.7% in patients aged 20 to 49 years and 8.9% in those aged 50 to 54 years (P > 0.1). Furthermore, and in the baseline low-risk adenoma group (n = 1,869), the 5-year risk of metachronous ACRN was 4.9% in those aged 20 to 49 years and 5.1% in those aged 50 to 54 years (P > 0.1) [37]. A case-control study in the United States also reported a similar risk of metachronous ACRN in patients aged 19 to 40 years (n = 128) and 50 to 84 years (n = 123) (older patients vs. younger patients: HR, 1.3; 95% CI, 0.5 to 3.0; P = 0.58) [38]. In another United States cohort study, the risk of metachronous ACRN in the 40 to 49 years age group (n = 1,036) was similar to that in the 50 to 59 years age group (n = 5,238) [39]. When compared with the ≥ 60 years age group (n = 5,813, reference), similar risks were found in the 40 to 49 years age group (aOR, 0.61; 95% CI, 0.41 to 0.92) and the 50 to 59 years age group (aOR, 0.71; 95% CI, 0.58 to 0.86) [39]. Lastly, an Israeli study compared the risk of metachronous ACRN in younger patients (< 50 years, n = 116) and older patients (50 to 74 years, n = 261) [40]. In this study, after advanced adenoma removal, the 3-year risk of metachronous ACRN was 8.3% and 7.7% in those aged < 50 and 50–74 years, respectively (P = 0.885), and after low-risk adenoma removal, the 5-year risk of metachronous ACRN was 8.9% and 13.3% in those aged < 50 and 50–74 years, respectively (P = 0.409) [40]. These four studies suggest that the intervals recommended in the current post-polypectomy surveillance guidelines for adults over 50 years of age may be appropriate for younger adults under 50 years of age [37–40]. Taken together, given the various results from previous studies, more research focused on young-onset colorectal adenoma is needed to determine the optimal surveillance interval for young adults aged < 50 years.

CONCLUSION

The incidence of CRC in young adults aged < 50 years has been on the rise in recent years. The prevalence of colon adenoma, a precursor of CRC, in this age group was also not negligible. The risk factors for CRN in young adults under the age of 50 are male sex, smoking, obesity, and metabolic syndrome, as in those over 50 years of age. Age and clinical risk factors can be considered when selecting CRC screening strategies (FIT or colonoscopy). Early colonoscopy may be beneficial in adults over the age of 40 with clinical risk factors or those over the age of 35 years with a positive FIT result. A combination of f-Hb concentration and clinical risk factors may be more effective for stratifying the risk for ACRN, and it may also be more useful for prioritizing persons who need early colonoscopy. Given that previous studies have reported that the risk of metachronous ACRN in young patients aged < 50 years with colorectal adenoma removed was lower than or similar to those aged ≥ 50 years, the surveillance intervals after polypectomy for young patients aged < 50 years may not need to be shorter than those recommended in current guidelines focused on those aged ≥ 50 years.
