Abstract. We present particle optical properties of stratospheric smoke layers observed with multiwavelength polarization Raman lidar over Punta Arenas (53.2° S, 70.9° W), Chile, at the southernmost tip of South America in January 2020. The smoke originated from the record-breaking bushfires in Australia. The stratospheric aerosol optical thickness reached values up to 0.85 at 532 nm in mid-January 2020. The main goal of this rapid communication letter is to provide first stratospheric measurements of smoke extinction-to-backscatter ratios (lidar ratios) and particle linear depolarization ratios at 355 and 532 nm wavelengths. These aerosol parameters are important input parameters in the analysis of spaceborne CALIPSO and Aeolus lidar observations of the Australian smoke spreading over large parts of the Southern Hemisphere in January and February 2020 up to heights of around 30 km. Lidar and depolarization ratios, simultaneously measured at 355 and 532 nm, are of key importance regarding the homogenization of the overall Aeolus (355 nm wavelength) and CALIPSO (532 nm wavelength) lidar data sets documenting the spread of the smoke and the decay of the stratospheric perturbation, which will be observable over the entire year of 2020. We found typical values and spectral dependencies of the lidar ratio and linear depolarization ratio for aged stratospheric smoke. At 355 nm, the lidar ratios were higher (75–112 sr, mean 97 sr) and the depolarization ratios were lower with values of 0.14–0.22 (mean 0.18). The determined depolarization ratios for aged Australian smoke are in very good agreement with respective ones for aged Canadian smoke, observed with lidar in stratospheric smoke layers over central Europe in the summer of 2017. The much higher 532 nm lidar ratios, however, indicate stronger absorption by the Australian smoke particles.

1 Introduction

Massive bushfires fueled by high, record-breaking temperatures were raging in southeastern Australia in the summer season of 2019–2020 after months of extreme drought (Australian Bureau of Meteorology, 2020). These were the worst wildfires in decades. The enormous fire activity triggered strong pyrocumulonimbus (pyro-Cb) convection (Fromm and Servranckx, 2003; Fromm et al., 2010) in the last days of December 2019 and in January 2020 as our analysis revealed (Himawari, 2020; Himawari-Kachelmann-Wetter, 2020; MODIS, 2020a). The pyro-Cb towers reached heights of up to 17 km (MODIS, 2020a) and lifted enormous amounts of fire smoke into the upper troposphere and lower stratosphere (UTLS) as will be discussed in Sect. 3. Absorp-
tion of sunlight by the black-carbon-containing smoke particles caused warming of the smoke layers and further ascent of the aerosol particles (Boers et al., 2010; de Laat et al., 2012). The prevailing westerly winds transported the smoke layers to South America within 8–14 d. The first stratospheric smoke layers of the 2019–2020 Australian burning season were detected with our lidar system over Punta Arenas, Chile, at the southernmost tip of South America on the evening of 5 January 2020 and since then almost continuously by the end of January 2020 (and still in July 2020). The layers over Punta Arenas reached heights of 25–30 km at the end of January caused by diabatic heating of the smoke layers.

Similar to the spread of the Canadian smoke which covered large parts of the lower stratosphere in the Northern Hemisphere in the summer and autumn of 2017 (Khaykin et al., 2018; Baars et al., 2019a; Hu et al., 2019; Kloss et al., 2019), we expect a strong perturbation in stratospheric aerosol conditions in the Southern Hemisphere in 2020. Similar to the Northern Hemispheric smoke event in 2017, the decay of the perturbation may last longer than 6 months (Baars et al., 2019b; Kloss et al., 2019). These significantly changed stratospheric aerosol conditions have the potential to sensitively influence radiative transfer (Boers et al., 2010; Ditas et al., 2018; Kloss et al., 2019; Yu et al., 2019), heterogeneous ice nucleation in cloud layers (Ulrich et al., 2017), and heterogeneous chemical reactions (Yu et al., 2019) by providing surfaces for, e.g., chlorine activation (McConnell and Jin, 2010). Furthermore, such events enrich the natural soot particle reservoir between 20 and 30 km (Renard et al., 2008).

The spaceborne CALIPSO (Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation) lidar (Winker et al., 2009; Omar et al., 2009; Khaykin et al., 2018; Kar et al., 2019) and the Aeolus lidar of the European Space Agency (ESA) (Stoffelen et al., 2005; ESA, 2008; Lux et al., 2020; Witschas et al., 2020; Ansmann et al., 2007; Flamant et al., 2008) will significantly contribute to the monitoring and documentation of the spread of the smoke across the Southern Hemisphere and of the decay of the stratospheric perturbation in 2020. Passive remote sensing – as used by Khaykin et al. (2018), Ansmann et al. (2018), Hu et al. (2019), and Kloss et al. (2019) – to characterize the record-breaking 2017 smoke event in the Northern Hemisphere will be used as well.

In this rapid communication letter, we present the first measurements of the particle extinction-to-backscatter ratio (lidar ratio) and particle linear depolarization ratio at 355 and 532 nm for aged stratospheric smoke originating from the extreme Australian bushfires. The observations were performed with our multiwavelength polarization Raman lidar system (Polly; described in the next section) in Punta Arenas in southern Chile. These lidar and depolarization ratios are required as input parameters in the data analysis and homogenization of the spaceborne CALIPSO and Aeolus lidar measurements which are conducted at different laser wavelengths, namely at 355 nm in the case of the Aeolus lidar and 532 nm in the case of the CALIPSO lidar. On the one hand, 532 nm lidar ratios are needed, e.g., to accurately retrieve height profiles of the smoke light-extinction coefficients and of smoke aerosol optical thickness (AOT) by means of the CALIPSO lidar. On the other hand, 355 nm particle depolarization ratios are required in the retrieval of the total particle backscatter coefficient and the lidar ratio at 355 nm from Aeolus observations (Baars et al., 2019a). Lidar ratios and depolarization ratios measured simultaneously at both 355 and 532 nm wavelengths are a prerequisite in efforts to successfully homogenize the overall Aeolus–CALIPSO data set of smoke optical properties later on. Simultaneously measured lidar ratios and depolarization ratios are also important parameters in aerosol typing efforts (see, e.g., Burton et al., 2012, 2015; Groß et al., 2013; Nicolaie et al., 2018; Papa- giannopoulos et al., 2018) with lidars from ground and in space to improve optical models developed to simulate the smoke optical properties as a function of particle shape and size characteristics and composition (e.g., Kahnert, 2017; Liu and Mishchenko, 2018, 2020; Luo et al., 2019; Gialitaki et al., 2020). Thus, our Punta Arenas lidar observations in January 2020 can be regarded as an important contribution to the global library of aerosol optical properties.

2 Lidar apparatus and data analysis

The lidar observations in Punta Arenas (53.2° S, 70.9° W; 9 m above sea level, a.s.l.), Chile, were conducted in the framework of the long-term DACAPO-PESO (Dynamics, Aerosol, Cloud And Precipitation Observations in the Pristine Environment of the Southern Ocean; https://dacapo.tropos.de, last access: 20 April 2020) campaign lasting from November 2018 to the end of 2020. The main goal of DACAPO-PESO is the investigation of aerosol–cloud interaction processes in rather pristine, unpolluted marine conditions. The mobile Leipzig Cloudnetsupersetse LACROS (Leipzig Aerosol and Cloud Remote Observation System; http://lacro.ges.rsd.tropos.de/, last access: 20 April 2020) (Bühl et al., 2013, 2016; LACROS, 2020) was run continuously at the University of Magallanes (UMAG) in Punta Arenas and covered two summer and winter seasons of aerosol and cloud observations. LACROS is equipped with a multiwavelength polarization Raman lidar, a wind Doppler lidar, a 35 GHz Doppler cloud radar, a ceilometer, a disdrometer, and a microwave radiometer. In addition, an AErosol RObotic NET-work (AERONET) sun photometer was operated (Holben et al., 1998; AERONET, 2020).

The Polly instrument (PÖrtabLle Lids Ystem) (Engelmann et al., 2016) is the key instrument of LACROS for aerosol profiling, and it is installed inside a container. This lidar has 13 channels and continuously measures elastic and Raman backscatter signals at the laser wavelengths of
3.1 Smoke transport from Australia to southern South America

The year 2019 was Australia’s warmest and driest year on record (Australian Bureau of Meteorology, 2020). These extreme conditions favored strong and long-lasting bushfires during the summer months of 2019–2020. Vigorous, deep pyro-Cb convection developed over the fire areas in southeastern Australia and lifted large amounts of smoke into the UTLS height range. We counted pyro-Cb events over southeastern Australia and the adjacent regions over the Pacific Ocean on more than 20 d during the 1-month period from 20 December 2019 to 20 January 2020 by analyzing satellite observations (Himawari, 2020; Himawari-Kachelmann-Wetter, 2020; MODIS, 2020a).

Based on a detailed forward and backward trajectory analysis (HYSPLIT, 2020), we distinguished three regimes of smoke transport. These regimes are highlighted in Fig. 1, and backward trajectories for case b in Fig. 1 are presented in Fig. 2. The first regime comprises smoke transport in the troposphere. Smoke injected over the source regions at heights below 10 km widely remained in the troposphere (Fig. 1a). Smoke injected into the UTLS regime at heights from about 12 km to about 16–17 km and remaining at heights below 19–20 km belong to the second transport regime. These smoke layers experienced fast eastward advection and reached Punta Arenas within about 10 d. Such a case is shown in Fig. 1b and will be discussed in more detail below. The smoke layers ascended during the transport by efficient diabatic heating as a result of the strong absorption of solar radiation by the black-carbon-containing smoke particles and partly entered the stratospheric range above 19–20 km height. Figure 1c shows an example representing this third regime of smoke transport. The smoke-containing air mass (in Fig. 1c) crossed the Pacific Ocean eastward to about 100° W within 6 d, according to HYSPLIT forward trajectories, starting at 37.1° S, 152° E, i.e., over the western Pacific close to the coast of southeastern Australia at heights of 12–17 km between 18 and 20 January 2020 (not shown). Caused by diabatic heating and lifting, the smoke layers reached heights above 19–20 km after about 6 d and moved forward with rather low speed. The backward trajectories for Punta Arenas with arrival heights from 20 to 28 km on 25–30 January showed many circular movements west and southwest of Punta Arenas. As a consequence, the air masses stayed southwest of and over Punta Arenas for about 5 d according to OMI (ozone monitoring instrument) observations (OMI, 2020) and left the region not before 30 January 2020. This extended smoke plume covered a region of about 2000 km (east to west) by 1000 km (north to south) and showed many 500 nm AOT pixels between 1 and 2 as a mean for the period from 20 to 31 January 2020 (OMI, 2020). The smoke layer in Fig. 1c with very sharp edges at 20.5 km (base) and 26 km height (top) belongs to this extended smoke field. We observed a stratospheric 532 nm AOT of about 0.35 on 29 January 2020. This opportunity was used to learn more about the ascent rate of the smoke. An almost monotonic lifting was recorded. The top height of the smoke layer ascended with a constant rate of 1 km d⁻¹ from 25 January (layer top at 22 km) to 30 January (layer top at 27 km). This unusual case will be further discussed in Sect. 3.2 based on Fig. 5.

https://doi.org/10.5194/acp-20-8003-2020
Figure 1. (a) Australian bushfire smoke in the troposphere, where the smoke layer extended from 6 to 11 km at 00:00 UTC and slowly descended with time, and in the stratosphere (a thin layer at 12.5 km in the beginning and at 14 km at the end on 6 January 2020). (b) Bushfire smoke in two layers from 13 to 15 km and from 16 to 18 km height on 10 January 2020. (c) Thin layers at 13 and 16 km and a dense bushfire smoke layer from 20 to 26 km height on 29 January 2020. The smoke was observed with the lidar in Punta Arenas, Chile, 10 000 km downwind of the Australian fire areas. The range corrected 1064 nm signal is shown. The tropopause heights according to the Punta Arenas radiosonde (launched at 12:00 UTC, 08:00 local time) are given as orange horizontal lines. Black, column-like filaments above cloud layers (shown as white areas) indicate strong laser pulse attenuation. The large, well-defined black columns (from surface to 20 km) indicate periods of automated depolarization calibration. The complex white areas in (a) above 4 km height indicate ice and mixed-phase clouds which caused ice virga formation (red and yellow). The clouds developed in smoke-containing air (green to blue with a few long-lasting coherent shallow smoke layers in yellow below and above the tropopause). These rather complex cloud features may be related to the occurrence of enhanced levels of smoke INPs (ice-nucleating particles) in the usually very pristine free troposphere with a low amount of very inefficient marine INPs (Kanitz et al., 2011).

Figure 2 provides an impression of the air mass transport from the forest fire regions in southeastern Australia to the southern part of South America. The respective smoke observation in Punta Arenas on 10 January 2020 is shown in Fig. 1b. We performed a detailed HYSPLIT trajectory analysis with 5–13 d forward trajectories starting close to the coast of southeastern Australia at heights from 12 to 17 km between 29 December 2019 and 1 January 2020 and 10–13 d backward trajectories arriving at Punta Arenas above the tropopause between 8 and 11 January 2020 (HYSPLIT, 2020). Based on the trajectory analysis together with the study of pyro-Cb events over southeastern Australia (Himawari, 2020; Himawari-Kachelmann-Wetter, 2020) and the corresponding Cb top heights, temperatures, and thus maximum possible smoke injection heights (MODIS, 2020a), the following synergistic picture on the smoke transport from southeastern Australia to the southern parts of South America between 28 December 2019 and 10 January 2020 was obtained. A period with coherent and intense pyro-Cb developments, triggered by the extreme fires, started on 28 December 2019 (00:00 UTC) and lasted for almost 4 d. The strongest pyro-Cb clusters occurred from 30 December, 07:00 UTC, to 31 December 2019, 12:00–15:00 UTC. Huge cloud complexes formed with horizontal extents of 150 km × 250 km to 350 km × 750 km (Himawari, 2020; Himawari-Kachelmann-Wetter, 2020), and the cloud tops partly reached 16–17 km height (MODIS, 2020a). These cloud towers lifted large amounts of smoke into the UTLS region, mostly up to 15–16 km height.

After the dissolution of the clouds, the released smoke absorbed solar radiation, heated the air, and probably ascended with a rate of about 1–2 km d$^{-1}$ during the first 3 d after injection as long as the stratospheric smoke AOT (at 550 nm) was on the order of 2 or more, as was the case according to satellite observations over the Pacific east of Australia (MODIS, 2020b; CALIPSO, 2020; Torres et al., 2020b). Torres et al. (2020b) reported 388 nm AOT values of 1 to > 5 in a large smoke field east of New Zealand on 2 January 2020. This smoke field was linked to the pyro-Cb activity over southeastern Australia on 30–31 December 2019. This smoke crossed Punta Arenas on 9–10 January 2020. After about 3 d, the ascent rate may have been much lower at much lower AOTs over the remote Pacific Ocean. We assume a further ascent of around 2 km during the residual 7 d of the travel towards Punta Arenas. This hypothesis of a strong ascent is in good agreement with modeling studies of ascent rates of Australian smoke layers originating from the rather strong Black Saturday fires (occurring on 7 February 2009 in the Melbourne area) by de Laat et al. (2012). A similar ascent of smoke layers by 5–8 km was observed with CALIPSO during the 10 d transport of smoke layers from the western Canadian fire sources to Leipzig, Germany, in mid-August 2017 (Torres et al., 2020a). Thus, all in all, the Australian smoke layers probably ascended by 5–7 km within 10 d on the way from southeastern Australia to Punta Arenas. This ascent has to
be taken into consideration in the interpretation of our backward trajectory computations which ignore any diabatic heating effect on air motion.

According to the backward trajectories in Fig. 2, the smoke injection heights were at about 16–17 km height over the identified pyro-Cb areas. This finding is in agreement with the discussion by Torres et al. (2020b) about smoke injection heights required to explain the presented satellite-based AOT observations east of New Zealand on 2 January 2020. All backward trajectories that crossed the pyro-Cb areas on 30–31 December 2019 at heights between 14 and 17 km (colored trajectories) arrived at Punta Arenas between about 11 and 13 km height (the 12.5 km trajectory ensemble is given in Fig. 2). These air masses descended by about 3–5 km on their transport over the 10 000 km distance because of the large-scale meteorological conditions. This descent of the smoke layers was then obviously overcompensated by the assumed ascent by 5–7 km so that finally the smoke was observed between 13 and 15 km height and not between 11 and 13 km as the backward trajectories suggested.

We observed another layer on 10 January 2020 (Fig. 1b; 16–18 km height). The respective backward trajectory analysis (not shown) indicates that this smoke layer needed about 2 d more than the lower smoke layer to reach Punta Arenas. The air masses had thus 2 d more to absorb solar radiation and thus to ascend to greater heights.

The CALIPSO observations analyzed from 19 December 2019 to 14 January 2020 (CALIPSO, 2020) corroborate our explanation of the smoke transport. A coherent flow of smoke from southeastern Australia to southern South America was found mainly in the stratosphere, including an increase in the smoke layer top height with increasing transport time. More details of the CALIPSO observations and comparison with our ground-based lidar measurements will be presented in a follow-up article focusing on the entire record-breaking stratospheric Australian smoke event in 2020.

It is worth noting that Foth et al. (2019) discuss a similar bushfire case observed with a Polly instrument at the same site of Punta Arenas in March 2010 (Kanitz et al., 2011). This case was associated with the occurrence of pyro-Cb over western Australia. Similar long-range transport characteristics were found for the smoke in the upper troposphere at about 12 km height over Punta Arenas in March 2010. The study was based on comprehensive atmospheric modeling in combination with CALIPSO lidar observations. The good agreement between the model results and the observations indicate that self-lifting effects were obviously rather weak in this case and could be ignored. Floutsi et al. (2020) summarized recent aerosol observations in the free troposphere over Punta Arenas (November 2018 to December 2019) and also found a smoke plume (at 11 km height) advected from southern Australia to Punta Arenas within 9–10 d in March 2019.

3.2 Lidar observations of smoke optical properties

Figure 3 presents an example of a lidar measurement of stratospheric smoke over Punta Arenas in January 2020. The full set of derivable smoke optical properties is shown. The 2-h mean profiles of the particle backscatter and extinction coefficients and respective extinction-to-backscatter ratios (lidar ratios), as well as of the particle linear depolarization ratios at 355 and 532 nm, are given, having been measured.
with the polarization Raman lidar Polly in the early morning of 9 January 2020. Signal smoothing was applied with window lengths of 500–700 m in the case of the backscatter coefficient and depolarization ratio profiles and 2000–2500 m in the case of the extinction coefficient and lidar ratio profiles. The backscatter coefficients were inter-calibrated in a thin cirrus layer between 6 and 8 km height assuming wavelength-independent cirrus backscattering and are thus very accurate. The results are noisy (especially for 355 nm, affected by strong Rayleigh attenuation) because the Polly lidar is designed and optimized for tropospheric aerosol observations and not just for the monitoring of stratospheric aerosol events as mentioned already by Baars et al. (2019b). Nevertheless, the layer mean values for the different optical parameters, highlighted as vertical lines in Fig. 3, provide a clear picture of the optical properties and the underlying shape, size, and composition characteristics of the aged stratospheric smoke particles. As is typical for aged smoke, the spectral dependency of the backscatter coefficient is strong, whereas the wavelength dependence of the extinction coefficient (for the short wavelength range from 355 to 532 nm) is weak. As a consequence, the lidar ratio is significantly larger at 532 nm compared to 355 nm. The measured depolarization ratios of around 0.2 (355 nm) and 0.15 (532 nm) are also typical for aged smoke for upper tropospheric and stratospheric heights, as was found by Burton et al. (2015), Haarig et al. (2018), and Hu et al. (2019). If the smoke particles would have had an ideal spherical shape (consisting of a black carbon core and a thick organic carbon shell), the depolarization ratio would have been close to zero (Haarig et al., 2018), as was observed for the Canadian smoke at heights in the middle troposphere. Slight deviations from the ideal spherical form in combination with the monomodal, narrow smoke size distribution (accumulation mode shifted to larger particles with a mode diameter of 600 to 700 nm, absence of a coarse mode) (Dahlkötter et al., 2014; Haarig et al., 2018) lead to the observed enhanced depolarization values and the distinct wavelength dependence, as recently modeled by Gialitaki et al. (2020) and also suggested by other modeling groups (e.g., Yu et al., 2019; Liu and Mishchenko, 2020). According to Yu et al. (2019), smoke particles consist of an insoluble black carbon (BC) core that is surrounded by an almost spherical shell of organic material and other atmospheric substances.

Table 1 summarizes seven analyzed smoke cases observed over Punta Arenas in January 2020. Layer mean values of geometrical and optical property layers for two pronounced smoke periods lasting from 8 to 11 January and from 25 to 30 January are given. During the second period (26–30 January), the analyzed smoke layers were at heights above 19–20 km (Sect. 3.1; smoke transport regime 3). The 387 nm Raman signal profiles were very noisy at heights above 20 km so that a retrieval of 355 nm smoke extinction profiles were no longer possible. Even the cross-polarized 355 nm signals were too noisy for a trustworthy determination of the respective depolarization ratio (28–30 January 2020). To provide at least estimated pairs of 355 and 532 nm lidar ratios even for these cases, we used accompanying Punta Arenas AERONET photometer observations of 380 and 500 nm AOTs (AERONET, 2020) to calculate the respective extinction wavelength dependence for the short wavelength range and applied this wavelength dependence to the 532 nm extinction profiles to estimate the respective profiles of the 355 nm smoke extinction coefficient. Afterwards we estimated the 355 nm smoke AOT and layer mean smoke lidar ratios by combining the measured 355 nm layer mean
Table 1. Smoke layer mean values of lidar ratios (LR) and depolarization ratios (DR) simultaneously measured at 355 and 532 nm on 3 subsequent days in January 2020. Tropopause height (TPH), layer base height (LBH), geometrical depth (LGD), and AOT of the stratospheric smoke layers are given in addition. Wavelength (in nm) is indicated in parentheses. The uncertainty in the layer mean values is mainly caused by signal noise estimated to be about 10% (DR, 532 nm), 20% (LR, 532 nm, DR, 355 nm), and 30% (LR, 355 nm). For comparison, values for aged Canadian smoke measured over Leipzig, Germany, in August 2017 are given in the last line (Haarig et al., 2018). AERONET photometer observation of AOT wavelength dependence for the short wavelength spectral range (380–500 nm) is used to estimate 355 nm smoke AOT, extinction coefficient, and lidar ratio from the lidar measurements at 532 nm. These values are also given in parentheses (26–30 January 2020).

Large lidar ratios of 75–112 sr were observed at 532 nm indicating strongly absorbing BC containing smoke particles. The lidar ratios at 355 nm were systematically lower, partly by more than 30 sr compared to the ones for 532 nm. This is an unambiguous indication for aged smoke. A review on smoke lidar ratios and depolarization ratios in the troposphere and stratosphere can be found in Haarig et al. (2018). The mean lidar ratios of the seven cases in Table 1 are 71 sr for 355 nm and 97 sr for 532 nm. For the depolarization ratios, we obtain mean values of 0.23 (355 nm) and 0.18 (532 nm). Without going into details here, which may be found in Ansmann et al. (2007), Wandinger et al. (2015), and Baars et al. (2019a), the Aeolus lidar transmitting circularly polarized laser pulses at 355 nm would have measured an apparent 355 nm lidar ratio of a factor of 1.6 higher than that observed with Polly, in this case with a particle depolarization ratio of 0.23 at 355 nm. In the case of the apparent lidar ratio, light-depolarization is ignored in the Aeolus data analysis.

Next, we compared the mean lidar ratios and depolarization ratios of the Australian bushfire smoke event with the

![Figure 4. Comparison of the spectral dependence of (a) the lidar ratio and (b) the particle linear depolarization ratio of aged Canadian and Australian smoke as measured in the stratosphere over Leipzig, Germany, on 22 August 2017 (open symbols) and over Punta Arenas, Chile, in January 2020 (closed symbols). In the case of the Australian smoke, mean values of the seven cases in Table 1 are shown, and the vertical bar indicates the full range of found values. In the case of the Canadian smoke values (measurement case from 22 August 2017), vertical bars show the retrieval uncertainty.](https://doi.org/10.5194/acp-20-8003-2020)
ones observed during the record-breaking Canadian smoke season in Leipzig, Germany, during the night of 22–23 August 2017 (see Table 1, last line). This comparison is highlighted in Fig. 4. The similarity of the spectral slopes of the lidar and depolarization ratios for stratospheric Canadian and Australian smoke after long-range transport over more than 10000 km in the Northern Hemisphere (2017) and in the Southern Hemisphere (2020) is surprising. Very similar depolarization ratio values point to the same shape and size characteristics of aged Canadian and Australian smoke in the stratosphere. Even the depolarization ratio at 1064 nm could be measured at the central European lidar station of Leipzig, Germany, in the case of Canadian smoke (Haarig et al., 2018). The strong wavelength dependence of the depolarization ratio from 355 to 1064 nm and the very low 1064 nm depolarization ratio values are a strong hint that coarse mode smoke particles were absent in the stratosphere.

In contrast to the Canadian and Australian smoke depolarization ratios, the lidar ratios are very different. This difference points to a much stronger light absorption by the Australian smoke particles and is probably related to the different burning material. Australian’s forests mainly consist of eucalyptus trees, whereas western Canadian tree types are predominantly pine, fir, aspen, and cedar. For completeness, high 532 nm lidar ratios were also observed in the case of wildfire smoke originating from central Africa (Tesche et al., 2011) and from South Africa (Giannakaki et al., 2016). The African lidar ratios for 355 and 532 nm were found to be almost equal (no pronounced wavelength dependence) which, in turn, is an indication that the measured smoke was relatively fresh (of regional origin), and not aged as observed over Punta Arenas.

Figure 5 (together with Table 1) provides a summarizing overview of our stratospheric lidar observations in Punta Arenas in January 2020. The evolution of the stratospheric perturbation over the southernmost tip of South America is shown in terms of 532 nm smoke AOT, the respective stratospheric mean 532 nm extinction coefficient, and the smoke lidar ratios for both wavelengths. The 355 nm lidar ratios in Fig. 5 are exclusively derived by means of the lidar–photometer retrieval method.

As can be seen in Fig. 5a, a two-layer structure developed with a lower layer at heights below about 18 km (Sect. 3.1, smoke transport regime 2) and above 18 km height (smoke transport regime 3). Vertical depths ranged from a few hundred meters up to several kilometers and partly reached values of 6 km. The depolarization ratio observations suggest even different smoke types (or different ages) with slightly different shape properties in the lower and upper layers. The higher depolarization ratios indicating less spherical particle shapes are found in the upper layer.

The ascent of the smoke layer above 20 km is visible between 25 and 30 January. As discussed in Sect. 3.1, this layer observed over Punta Arenas was part of a large smoke field (with an extent of 1000 km × 2000 km). According to OMI (2020), the mean 500 nm AOT was around 0.6–0.7 in this smoke field for the 20–31 January period, and mean peak values were close to 2. Punta Arenas was always at the rim of the smoke area. The lidar measured the highest stratospheric 532 nm AOTs of 0.25–0.35 on 28–30 January 2020. As can be seen in Fig. 5a, the top height of the smoke layer steadily moved upward by 1 km d⁻¹ from 25 to 30 January 2020. Such a strong ascent rate of 1 km d⁻¹ was also found by de Laat et al. (2012) for the Black Saturday fire smoke in February 2009, however for AOTs close to 3.5. Ascent rates of about 1 km d⁻¹ were also derived from CALIPSO observations for the optically dense Canadian smoke layers in the
summer 2017 during the first 5 d of long-range transport after
the injection into the UTLS region on 13 August 2017 (Tor-
res et al., 2020a). It should be mentioned that the backward
trajectories arriving at Punta Arenas did not indicate any dy-
namically induced lifting during the 20–31 January 2020 pe-
riod so that the observed ascent is probably entirely the re-
sult of the absorption of solar radiation by the black-carbon-
containing smoke particles.

Figure 5b shows that the 532 nm AOT was above the stratospheric background level of 0.002 by 1–2 orders of magnitude in January 2020. Sakai et al. (2016) present strato-
spheric aerosol backscatter observations for Lauder, New Zealand, from 1992 to 2015. By assuming a typical lidar ra-
tio of 50 sr at 532 nm for stratospheric sulfuric acid droplets, the minimum column-integrated backscatter coefficients of
Lauder correspond to minimum stratospheric AOT values of
0.002 (see dashed line in Fig. 5b).

The highest smoke-related 532 nm AOT value of 0.85 was
found in the morning of 17 January 2020. The profile of the
smoke backscatter coefficient was multiplied by the 532 nm
smoke lidar ratio of 95 sr to obtain an estimate for the 532 nm
AOT. For a lidar ratio of 80 sr (also a realistic smoke lidar ra-
tio), the stratospheric AOT would decrease to 0.71, a value
close to the maximum 532 nm AOT of 0.6 observed over
Leipzig during the midday hours on 22 August 2017 when the
densest Canadian smoke plumes crossed Leipzig. The
532 nm AOT remained high with most values from 0.02 to
0.2 in January 2020. Most smoke extinction coefficients were
on the order of 10–100 Mm$^{-1}$ in January 2020.

Finally, Fig. 5d shows the derived lidar ratios which were
high with values mostly between 75 and 112 sr at 532 nm and
much lower values for the wavelength of 355 nm. As men-
tioned, this unique wavelength dependence is a clear signa-
ture for aged smoke after long range transport. The opposite
is the case, e.g., for urban haze and anthropogenic particles
in general. Then the 355 nm lidar ratio is significantly higher
than the 532 nm lidar ratio (Müller et al., 2005, 2007).

The ongoing lidar observations in Punta Arenas presently
(until July 2020) show a very pronounced and geometrically
deep smoke layer from about 10 to 20 km height, and fre-
quently thin layers around 25 km height. The AOT values are
still clearly above the background value. The stratospheric
perturbation in the Southern Hemisphere, triggered by sev-
eral periods with strong pyro-Cb activity over the south-
eastern Australian region in December and January 2020,
was much stronger than the one in the Northern Hemisphere
in the summer and autumn of 2017, which was related to
only one strong pyro-Cb event which occurred on 12–13 Au-
gust 2017 over western Canada (Peterson et al., 2018; Hu
et al., 2019; Torres et al., 2020a).

4 Conclusion and Outlook

Important input parameters required for a trustworthy
CALIPSO and Aeolus lidar data analysis of the stratospheric
Australian smoke observations have been presented. Strong
perturbations in stratospheric aerosol conditions with AOT
up to 0.85 at 532 nm were recorded with lidar in Punta Are-
asas, Chile, in January 2020. The stratospheric smoke depo-
larization ratios of the Australian fire particles were found
to be very similar to the ones observed over Europe in
aged Canadian smoke in the summer of 2017. Mean values
were 0.23 at 355 nm and 0.18 at 532 nm. However, Aus-
tralian smoke showed much higher lidar ratios (75–112 sr at
532 nm) compared to the Canadian smoke lidar ratios, which
indicates stronger light absorption. As is typical for aged
smoke, the smoke lidar ratios at 355 nm were lower by 20–
30 sr, partly > 30 sr compared to the values at 532 nm.

The Polly observations will be ongoing until the end of the
DACAPO-PESO campaign in late 2020 and thus will cover
the entire bushfire season and most of the decay phase of
the stratospheric perturbation in the Southern Hemisphere.
As an outlook, follow-up publications are planned concern-
ing the entire documentation of the unique smoke conditions
in the troposphere and stratosphere over southern Chile in
2019 and 2020. This will include the analysis of CALIPSO
and Aeolus lidar observations to describe the spread of the
smoke in the Southern Hemisphere. We are also working on a
detailed comparison of the record-breaking Northern Hemi-
spheric smoke event (2017) with this record-breaking strato-
spheric perturbation in the Southern Hemisphere.

It is expected that the significantly increased particle con-
centration in the free troposphere over southern South Amer-
ica sensitively influenced cloud evolution and precipitation
formation in this region with usually very low particle con-
centration of marine origin. Regarding future aerosol–cloud
interaction studies in the framework of the DACAPO-PESO
campaign, we plan to distinguish and separate time periods
with and without smoke pollution from Australia to evaluate
the potential impact of smoke on the occurrence and devel-
opment of liquid-water, mixed-phase, and ice clouds and
to continue in this way with our aerosol and cloud studies we
started 10 years ago (Kanitz et al., 2011; Foth et al., 2019).

Data availability. Polly lidar observations (level 0 data, measured
signals) are in the PollyNet database http://polly.rsd.tropos.de/
(PollyNET, 2020). LACROS observations (level 0 data) are stored
in the Cloudnet database (http://lacros.rsd.tropos.de, LACROS,
2020). All the analysis products are available at TROPOS upon
request (info@tropos.de). Backward trajectory analysis has been
supported by air mass transport computation with the NOAA
(National Oceanic and Atmospheric Administration) HYSLIT
(HYbrid Single-Particle Lagrangian Integrated Trajectory) model
http://ready.arl.noaa.gov/HYSPLIT_traj.php (HYSLIT, 2020).
CALIPSO observations of smoke profiles and smoke AOTs are used
(CALIPSO, 2020; FIRMS, 2020), as well as pyro-Cb cloud cluster

https://doi.org/10.5194/acp-20-8003-2020
satellite observations https://himawari8.nict.go.jp/ (Himawari, 2020), https://kachelmannwetter.de/de/sat/newsouthwales/top-alarm-10min/20200123-1150z.html (Himawari-Kachelmann-Wetter, 2020), and https://go.nasa.gov/2YdOaYH (MODIS, 2020a). The fire information used is provided by FIRMS (Fire Information for Resource Management System) (FIRMS, 2020).

Author contributions. The paper was written by KO and AA. The data analysis was performed by KO supported by HB, AA, AF, MH, and UW. All other co-authors are involved in the DACAPO-PESO campaign and took care of all measurements during several 4-week expeditions.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. We thank AERONET for their continuous efforts in providing high-quality measurements and products. Aerosol source apportionment analysis has been supported by air mass transport computation with the NOAA (National Oceanic and Atmospheric Administration) HYSLIP (HYbrid Single-Particle Lagrangian Integrated Trajectory) model. We also thank the Himawari 8, Kachelmann-Wetter, CALIPSO, MODIS, VIIRS, and OMI teams for their well-organized easy-to-use internet platforms. Analyses and visualization tools were made available via the Giovanni online data system, developed and maintained by NASA’s GES DISC. The MODIS and VIIRS information from the fires was provided by LANCE FIRMS operated by NASA, GSFC, and EOSDIS.

Financial support. TROPOS is involved in the Calibration/Validation (Cal/Val) activities of the Aeolus space mission in the frame of the German initiative EVAA (Experimental Validation and Assimilation of Aeolus observations) funded by the German Federal Ministry for Economic Affairs and Energy (BMWi) under grant no. (FKZ) 50EE1721C. The authors are also thankful for support through the European Research Infrastructure for the observations of Aerosol, Clouds, and Trace Gases Research Infrastructure (ACTRIS) under grant agreement no. 654109 and 739530 from the European Union’s Horizon 2020 research and innovation program. We thank AERONET-Europe for providing an excellent calibration service. AERONET-Europe is part of the ACTRIS project. The DACAPO-PESO observations are partly funded by the German Science Foundation (DFG) project PICNICC under project number 408008112.

The publication of this article was funded by the Open-Access Fund of the Leibniz Association.

Review statement. This paper was edited by Manvendra K. Dubey and reviewed by Michael Fromm and one anonymous referee.
