The dimensionless kinetic energy dissipation rate $C_\varepsilon$ is estimated from numerical simulations of statistically stationary isotropic box turbulence that is slightly compressible. The Taylor microscale Reynolds number ($Re_\lambda$) range is $20 \lesssim Re_\lambda \lesssim 220$ and the statistical stationarity is achieved with a random phase forcing method. The strong $Re_\lambda$ dependence of $C_\varepsilon$ abates when $Re_\lambda \approx 100$ after which $C_\varepsilon$ slowly approaches $\approx 0.5$, a value slightly different to previously reported simulations but in good agreement with experimental results. If $C_\varepsilon$ is estimated at a specific time step from the time series of the quantities involved it is necessary to account for the time lag between energy injection and energy dissipation. Also, the resulting value can differ from the ensemble averaged value by up to $\pm 30\%$. This may explain the spread in results from previously published estimates of $C_\varepsilon$.

I. INTRODUCTION

The notion that the mean turbulent kinetic energy dissipation rate $\varepsilon$ is finite and independent of viscosity $\nu$ was originally proposed by G. I. Taylor. Its importance is so recognized now that it is commonly referred to as the “zeroth law” of turbulence. Its existence was assumed by von Kármán and Howarth, Loitsianskii and also, significantly, Kolmogorov in establishing his celebrated similarity hypotheses for the structure of the inertial range of turbulence. Kolmogorov assumed the small scale structure of turbulence to be locally isotropic in space and locally stationary in time - which implies the equality of turbulent kinetic energy injection at the large scales with the rate of turbulent kinetic energy dissipation at the small scales. Although this view should be strictly applied only to steady turbulence, the mechanism of the dissipation of turbulent kinetic energy can be considered the most fundamental aspect of turbulence not only from a theoretical viewpoint but also from a turbulence modeling viewpoint. Indeed, the mechanism that sets the level of turbulent dissipation in flows that are unsteady is a difficult, if not intractable, aspect of turbulence modeling.

The rate of turbulent kinetic energy dissipation is determined by the rate of energy passed from the large-scale eddies to the next smaller scale eddies via a forward cascade until the energy is eventually dissipated by viscosity. Thus, $C_\varepsilon$ defined as,

$$C_\varepsilon = \frac{\varepsilon L}{u'^3}, \quad (1)$$

(here, $\varepsilon$ is the mean energy dissipation rate per unit mass, $L$ and $u'$ are characteristic large length and velocity scales respectively) should be independent of the Reynolds number and of order unity. An increase in Reynolds number should only result in an increase in the typical wave number where dissipation takes place. In the past few years there have been a number of numerical (see Ref. and references therein) and experimental (see Refs. for recent results) efforts to determine the value of $C_\varepsilon$ and its dependence on the Reynolds number. Perhaps the most convincing of these are the numerical attempts since there is no re-course to one-dimensional...
surrogacy as there is for experiments. Notwithstanding this fact, there is good agreement, both numerically and experimentally, with the long held view that \( C_{\epsilon} \) is \( \sim O(1) \) when the Reynolds number is sufficiently high. The collection of isotropic simulation results for \( C_{\epsilon} \) shown in Ref. 3 indicates that “high enough” Reynolds number appears to be \( \text{Re}_x \sim O(100) \). Here, \( \text{Re}_\lambda = u' v' / \nu \) is the Taylor microscale Reynolds number. At higher \( \text{Re}_\lambda \), slow \( \text{Re}_\lambda \) dependencies for \( C_{\epsilon} \), such as that proposed by Lohse[1] cannot be ruled out. Measuring such \( \text{Re}_\lambda \) dependencies, either numerically or experimentally, will be close to impossible.

One unresolved issue is that raised by Sreenivasan[10]. After assembling all the then known experimental decaying grid turbulence data[11] and numerical data for both decaying and stationary isotropic turbulence he concludes that “the asymptotic value (of \( C_{\epsilon} \)) might depend on the nature of large-scale forcing, or, perhaps, on the structure of the large scale.” He also demonstrates[12] in homogeneously sheared flows that the large structure does influence \( C_{\epsilon} \). However, it might be argued that these results were obtained at low Reynolds numbers and the issue of a universal asymptotic value for \( C_{\epsilon} \) could still be considered open. Alternatively it could be argued that homogeneous shear flows and the like are strictly unsteady turbulent flows and the zeroth law, in its simplest guise, should not be expected to apply to such flows. The possibility of some characteristics of large-scale turbulence being universal should not be ruled out. The recent observation that input power fluctuations, when properly re-scaled, appear universal[13] may be construed to suggest the possibility of universality for \( C_{\epsilon} \). The aim of the present work is to estimate \( C_{\epsilon} \) from direct numerical simulations (DNS) of statistically stationary isotropic turbulence and compare with previously reported DNS results (summarized in Fig. 3 of Ref. 3) and experiments carried out in regions of low \( (dU/dy) \approx (dU/dy)_{\text{max}}/2 \) or zero mean shear. The present DNS scheme differs from methods already reported in that a high-order finite difference method is used. To our knowledge, these are the first finite difference results for \( C_{\epsilon} \). Hence, it is worthwhile to test if different numerics and forcing at the large scales result in vastly different values for \( C_{\epsilon} \) to those already reported.

II. NUMERICAL METHODS

The data used for estimating \( C_{\epsilon} \) are obtained by solving the Navier-Stokes equations for an isothermal fluid with a constant kinematic viscosity \( \nu \) and a constant sound speed \( c_s \). The governing equations are given by

\[
(\partial_t + \mathbf{u} \cdot \nabla) \mathbf{u} = -\nabla \ln \rho + \mathbf{f}_{\text{visc}} + \mathbf{f}
\]

(2)

\[
(\partial_t + \mathbf{u} \cdot \nabla) \ln \rho = -\nabla \cdot \mathbf{u}.
\]

(3)

The viscous force is

\[
f_{\text{visc}} = \nu \left( \nabla^2 \mathbf{u} + \frac{1}{3} \nabla \nabla \cdot \mathbf{u} + 2\nu \mathbf{S} \cdot \nabla \ln \rho \right),
\]

(4)

where \( \mathbf{S}_{ij} = \frac{1}{2}(u_{i,j} + u_{j,i}) - \frac{\nu}{\lambda} \delta_{ij} \nabla \cdot \mathbf{u} \) is the traceless rate of strain tensor. In the numerical simulations the system is forced (stirred) using random transversal waves given by

\[
f(x, t) = f_0 e \cos [k(t) \cdot x + i\phi(t)],
\]

(5)

where \( k(t) \) is a wave number with magnitude between 1 and 2, while \( \phi(t) \) is a phase between \(-\pi \) and \( \pi \). Both \( \phi(t) \) and \( k(t) \) are chosen randomly at each time step giving a forcing that is delta-correlated in time. The random unit vector \( e \) is perpendicular to \( k \) and the forcing amplitude \( f_0 \) is chosen such that the root mean square Mach number for all runs is between 0.13 and 0.15 which is not too dissimilar to that found in the wind-tunnel experiments to be discussed in the next section. For these weakly compressible simulations, the energies of solenoidal and potential components of the flow have a ratio \( E_{\text{pot}}/E_{\text{sol}} \sim 10^{-4} \)–\( 10^{-2} \) for most scales; only towards the Nyquist frequency (henceforth \( k_{\text{max}} \)) does the ratio increase to about 0.1. It is thus reasonable to assume that compressibility is irrelevant for the results presented here whilst at the same time the present results can be considered more comparable and relevant to experimental wind tunnel flows than the perfectly incompressible simulations published so far. The code has been validated in previous turbulence studies and the reader is referred to Refs. 14, 12, 16 and the code web-site 17 for more information.

The simulations are carried out in periodic boxes with resolutions in the range of \( 32^3 \)–\( 512^3 \) grid points. The box size is \( L_x = L_y = L_z = 2\pi \), which discretizes the wave numbers in units of 1. The viscosity \( \nu \) is chosen such that the maximum resolved wave number \( k_{\text{max}} \) is always greater than \( 1.5/\eta \), where \( \eta = (\nu^3/\epsilon)^{1/4} \) is the Kolmogorov length scale.

To be consistent with previously published DNS studies, the total kinetic energy \( E \) is defined as

\[
E_{\text{tot}} = \frac{1}{2} \left( \mathbf{u}^2 \right) = \frac{3}{2} \mathbf{u}^2 = \int_0^{k_{\text{max}}} E(k) dk,
\]

(6)

the integral length scale \( L \) is defined,

\[
L = \frac{\pi}{2u' \nu^2} \int_0^{k_{\text{max}}} k^{-1} E(k) dk,
\]

(7)

and the average turbulent energy dissipation rate is defined as

\[
\epsilon = 2\nu \int_0^{k_{\text{max}}} k^2 E(k) dk.
\]

(8)

Angular brackets denote averaging over the box volume. After each run has become statistically stationary (typically 1-2 eddy turnovers \( T \approx L/u' \)) the average statistics are estimated for the remaining total run time. Table IV summarizes the average statistics for each run. Comparing Runs C and D in Table IV indicates that there is little difference in the average \( C_{\epsilon} \) for simulations resolved up to \( \eta k_{\text{max}} = 1.5 \) from \( \eta k_{\text{max}} = 3 \).
TABLE I: Examples of DNS parameters and average turbulence characteristics. \( N \) is the number of grid points in each of the Cartesian directions, \( \text{Re}_\lambda \) is the Taylor microscale Reynolds number \( \equiv u' \lambda / \nu \), \( T_{tot} \) is the total run time after the run became statistically stationary, \( T \) is the eddy turnover time \( \equiv L / u' \), \( \Delta t \) is the run time increment, \( t_\epsilon \) is the Kolmogorov time scale \( \equiv \nu^{1/2} \epsilon^{-1/2} \), \( \lambda \) is the Taylor microscale \( \equiv u' \sqrt{15 \nu / \epsilon} \), \( \tau_{max} \) is the average time for the energy cascade from large to small scales, and \( \eta \) is the Kolmogorov length scale \( \equiv \nu^{3/4} \epsilon^{-1/4} \).

III. RESULTS

A. Numerical results

In this section results for the higher order finite difference numerical simulations are presented. The simulations began with \( N = 32^3 \) and each subsequent larger box size began with a velocity field interpolated from the previous box size. Figures 1a)-(d) show example time series from Run E \( (N = 256^3) \) for the fluctuating velocity \( u \), the fluctuating integral length scale \( L \), the fluctuating kinetic energy dissipation rate \( \epsilon \) and the fluctuating Reynolds number \( \text{Re}_\lambda \) respectively. Initially, the turbulence takes a short amount of time to reach a statistically stationary state - a consequence of stabilizing the new run from the previously converged run. The fluctuating quantities shown in Figures 1a)-(d) are not unlike those encountered in a wind tunnel. Indeed, Fig. 1a) could easily be mistaken for a hot-wire trace of a turbulent flow. This is in stark contrast to some pseudo-spectral methods that use negative viscosity to maintain a constant energy level. For example, it is worth comparing Figs. 1b)-(d) with those shown in Ref. [18] [i.e. their Figs. (2)-(7)]. The pseudo spectral results show that the same quantities only fluctuate with a comparatively long period.

Given that the statistics are fluctuating, although they are statistically stationary, it is tempting to plot the instantaneous \( C_\epsilon \) as a function of \( \text{Re}_\lambda \). Figure 2 shows \( C_\epsilon \) calculated in such a way. The \( \text{Re}_\lambda \) dependent trends are obviously not as expected. However, it is worth noting the apparent range for \( C_\epsilon \) when \( \text{Re}_\lambda \gtrsim 50 \) is \( 0.3 - 0.7 \) which is the range of previously published DNS results. This may explain the scatter in previously published DNS results if \( C_\epsilon \) is calculated from a subjective choice of \( \epsilon \), \( L \) and \( u' \) at a single time step e.g. as in Ref. [5]. The reason for the incorrect \( \text{Re}_\lambda \) dependence for \( C_\epsilon \) can be gleaned from Figs. 1a) and (b). Figure 1a) shows that an intense burst in turbulent kinetic energy \( u^2 \) (an example is noted by the arrow) can be observed some maximum time lag \( \tau_{max} \) later in the turbulent kinetic energy dissipation rate [Figure 1b), again noted by an arrow]. More about the significance of \( \tau_{max} \) will be discussed later in Section III. By noting that there is a strong correlation between intense events of \( u^2 \) and \( L \) on the one hand and \( \epsilon \) on the other hand it is possible to estimate \( \tau_{max} \) from the maximum in the correlation between \( u'^3/L \) and \( \epsilon \) by

\[
\rho_{u'^3/L,\epsilon}(\tau) = \frac{[u'^3(t)/L(t)] [\epsilon(t+\tau)]}{u'^3(t)/L(t) \epsilon(t+\tau)},
\]

Figure 3 shows an example for Run E. The maximum time lag \( \tau_{max} \) corresponding to the maximum in \( \rho_{u'^3/L,\epsilon} \) is indicated by the up arrow ↑.
With this done for all runs it is possible to shift the time series of \( \varepsilon(t) \) for each run by its respective \( \tau_{\text{max}} \) and correctly calculate the instantaneous magnitude of \( C_\varepsilon \). Figure 2 shows the newly calculated \( \text{Re}_\lambda \) dependence of \( C_\varepsilon \) using the correct time lag \( \tau_{\text{max}} \) for each of the runs. A number of comments can be made. Firstly, the dimensionless dissipation rate \( C_\varepsilon \) appears to asymptote when \( \text{Re}_\lambda \gtrsim 100 \). The asymptotic magnitude \( C_\varepsilon \approx 0.5 \) is in good agreement with the consensus DNS results published so far i.e. \( C_\varepsilon \approx 0.4 \) to 0.5. (see Refs. \[5\] and references therein). Having said this and given the present demonstration that it is incorrect to estimate \( C_\varepsilon \) from a single time snapshot it would be interesting to recalculate previously published results based on subjective choices of the quantities involved for estimating \( C_\varepsilon \) by using the entire time series. Lastly, the present results verify the use of a high-order finite difference scheme and also prove that the zeroth law applies to slightly compressible turbulence.

![Graph showing \( C_\varepsilon \) as a function of \( \text{Re}_\lambda \)](image)

**FIG. 2:** Incorrectly estimated \( C_\varepsilon \) as a function of \( \text{Re}_\lambda \). +, Run A; \( \triangledown \), Run B; \( \times \), Run C; \( \square \), Run D; \( \odot \), Run E; \( \triangle \), Run F. Ensemble averages can be found in (Table I).

Having estimated \( \tau_{\text{max}} \) and assuming it approximates the average time \( \tau \) for the energy to cascade from the large energetic scales to the small dissipative scales it is worth comparing the present results with a simple cascade model such as that discussed by Lumley [2]. Using a forward cascade model, whereby the spectrum is divided logarithmically into eddies which have the same width in wave number space as their center wave number, the total time taken for energy to cross the spectrum, assuming that all energy is passed directly to the next wave number,

\[
\tau = \tau_{\text{max}} = 2 \left( \frac{L}{u'_r} \right) \left( 1 - 1.29 \sqrt{15/\text{Re}_\lambda^2 C_\varepsilon} \right).
\]

Here, we have substituted \( (15/\text{Re}_\lambda^2 C_\varepsilon)^{\frac{1}{2}} \) for Lumley’s large scale Reynolds number dependence \( \text{Re}_L^{-1/2} \). In non-dimensional form,

\[
\tau^+ = 2 \left( 1 - 1.29 \sqrt{15/\text{Re}_\lambda^2 C_\varepsilon} \right). \tag{10}
\]

As noted by Lumley, little attention should be paid to the numerical values of the coefficients, though attention should be paid to the exponent for \( \text{Re}_\lambda \). For small values of \( \tau^+ \), e.g. \( \tau^+ < 1 \), the large scale energy is directly affected by viscosity and has little chance of transferring energy in a classical cascade manner, whilst for large values of \( \tau^+ \), e.g. \( \tau^+ > 1 \), the large scales have the time for grinding down energy unaffected by viscosity. The asymptotic assumption of Eq. (10) is 2 eddy turnovers. Figure 3(a) shows the \( \text{Re}_\lambda \) dependence of \( \tau^+ \) compared with Eq. (10). The present results are much lower than the prediction of Eq. (10) and this is probably indicative of the fact that the energy cascade is not a simple full transfer of energy between neighboring wave numbers, for low \( \text{Re}_\lambda \) at least. It is more likely that, whilst most of the energy is passed to neighboring wave numbers, a diminishing amount of the energy is passed to all higher wave numbers. What is noticeable from the present results is that \( \tau^+ \approx 1 \) will not occur until \( \text{Re}_\lambda \approx 300 \) which is an \( \text{Re}_\lambda \) at which the \( \text{Re}_\lambda \) dependence of \( C_\varepsilon \) will become either numerically or experimentally, unmeasurable. There is no reason not to expect that at high enough \( \text{Re}_\lambda \) full energy transfer may occur between neighboring wave numbers. Using Eq. (10), Fig. 3 indicates that not until \( \text{Re}_\lambda \sim O(10^4) \) will \( \tau^+ \approx 2 \).

**B. Experimental results revisited**

Results for the present experiment, originally published in Ref. [6], are updated here with more data within the range \( 170 \lesssim \text{Re}_\lambda \lesssim 1210 \). Detailed experimental conditions can be found in Refs. [5, 6] and need not be repeated here. The main group of measurements are from a geometry called a NORMAN grid which generates a decaying wake flow. The geometry is composed of a perforated

![Graph showing \( \rho_{\text{diss}} \) as a function of \( \nu T \)](image)

**FIG. 3:** An example of the correlation \( \rho_{u'3/L, \varepsilon} \), Eq. (2), for Run E \( N = 256^3 \). The up arrow \( \uparrow \) indicates the location of \( \tau_{\text{max}}/T \approx 0.74 \).
plate superimposed over a bi-plane grid of square rods. The flow cannot be classed as freely decaying as the extent of the wind tunnel cross section (1.8 × 2.7 m²) is approximately 7 × 11 $L^2$. For all the flows presented in Ref. 3, signals of the fluctuating longitudinal velocity $u$ are acquired, for the most part, on the mean shear profile centerline. For the NORMAN grid, some data is also obtained slightly off the center-line at a transverse distance of one mesh height where $dU/dy \approx dU/dy|_{\text{max}}/2$.

All data are acquired using the constant temperature anemometry (CTA) hot-wire technique with a single-wire probe made of 1.27μm diameter Wollaston (Pt-10% Rh) wire. The instantaneous bridge voltage is buck-and-gained and the amplified signals are low-pass filtered $f_{lp}$ with the sampling frequency $f_s$ always at least twice $f_{lp}$. The resulting signal is recorded with 12-bit resolution. Time lags $\tau$ and frequencies $f$ are converted to streamwise distance ($\equiv \tau U$) and one-dimensional longitudinal wave number $k_1$ ($\equiv 2\pi f/U$) respectively using Taylor’s hypothesis. The mean dissipation rate $\varepsilon$ is estimated assuming isotropy of the velocity derivatives i.e. $\varepsilon \equiv \varepsilon_{\text{iso}} = 15\nu \langle \partial u/\partial x \rangle^2$. We estimate $\langle \partial u/\partial x \rangle^2$ from the average value of $E_{1D}(k_1)$ the 1-dimensional energy spectrum of $u$ such that $u^2 = \int_0^\infty E_{1D}(k_1)dk_1$ and from finite differences $\langle (\partial u/\partial x)^2 \rangle = (u_{i+1} - u_i)^2/(U f_s)^2$.

No corrections for the decrease in wire resolution associated with an increase in $Re_{\lambda}$ are made since all methods known to us rely on an assumed distribution for the three-dimensional energy spectrum. For most of the data, the worst wire resolution is $\approx 2\eta$ where $\eta$ is the dissipative length scale $\equiv \nu^{3/4}\varepsilon_{\text{iso}}^{-1/4}$. The present investigation is limited to one-dimensional measurements and suitable surrogates for Eq. 11. Although caution should be exercised when higher-order moments of a one-dimensional surrogate are substituted for the three-dimensional equivalent, the use of the mean quantity $\varepsilon_{\text{iso}}$ for $\varepsilon$ should not be too problematic here. The characteristic length-scale of the large-scale motions $L$ is $L_p$ and is estimated from the wave number $k_{1,p}$ at which a peak in the compensated spectrum $k_1E_{1D}(k_1)$ occurs i.e. $L_p = 1/k_{1,p}$ [4, 19]. As well the NORMAN grid data, the recent cryogenic decaying grid turbulence of Yeo [17] measured using the particle image velocimetry (PIV) technique are included.

FIG. 5: Correctly estimated $C_\varepsilon$ as a function of $Re_{\lambda}$. +, Run A; ∇, Run B; ×, Run C; □, Run D; φ, Run E; △, Run F. Ensemble averages can be found in (Table I).

FIG. 6: $Re_{\lambda}$ dependence of inertial range quantities. φ, the non-dimensional time lag $\tau_{\text{max}} = \tau_{\text{max}}/T$; ——, Eq. (10).

Figure 7 shows $C_\varepsilon$ for the present data and that of Ref. [4]. For all of the data, a value of $C_\varepsilon \approx 0.5$ appears to be the average value. It should be noted that estimates of $C_\varepsilon$ from the cryogenic decaying grid data are based on the transverse equivalents of the quantities that constitute Eq. (11). The majority of the scatter for the cryogenic data is due to the uncertainty of $L$ which is extremely difficult to estimate from PIV data. Figure 7 confirms that $C_\varepsilon$, albeit a one-dimensional surrogate, measured in a number of different flows is independent of $Re_{\lambda}$. It could be argued that the rate of approach to an asymptotic value depends on the flow e.g. proximity to initial and boundary conditions. The asymptotic value $C_\varepsilon \approx 0.5$ is in excellent agreement with the present DNS results. These experimental results are encouraging considering that wind-tunnel turbulence is always relatively young.

FIG. 4: Example of the offset time series for Run E ($\tau_{\text{max}}^+ \approx 0.74$), $N = 256^3$, average $Re_{\lambda} \approx 150$. Note that the peak events are now well correlated. ——, $u^3/L(t/T)$; ——, $\varepsilon\langle t - \tau_{\text{max}}^+ \rangle/T$.
compared to DNS turbulence, e.g. the Norman grid turbulence has only of the order of 6 eddy turnover times in development by the time it reaches the measurement station.

FIG. 7: Normalized dissipation rate $C_\varepsilon$ for different experimental flows. $\square$, circular disk, $154 \lesssim R_{\infty} \lesssim 188$; $\diamond$, golf ball, $70 \lesssim R_{\infty} \lesssim 146$; $\triangledown$, pipe, $70 \lesssim R_{\infty} \lesssim 178$; $\bigcirc$, normal plate, $79 \lesssim R_{\infty} \lesssim 335$; $\bigtriangleup$, Norman grid N1, $152 \lesssim R_{\infty} \lesssim 506$; $\times$, Norman grid N2 (slight mean shear, $dU/dy \approx dU/dy|_{max}/2$), $607 \lesssim R_{\infty} \lesssim 1215$; $\triangleright$, Norman grid N2 (zero mean shear), $388 \lesssim R_{\infty} \lesssim 1120$; $\prec$, decaying cryogenic grid turbulence, $127 \lesssim R_{\infty} \lesssim 376$.

IV. FINAL REMARKS AND CONCLUSIONS

The present work has revisited the zeroth law of turbulence for both numerical simulations of statistically stationary isotropic turbulence and experiments. The numerical simulations are slightly compressible isotropic turbulence and the statistical stationarity is achieved with a random phase forcing applied at low wave numbers. The main result of the numerical simulations is the demonstration that $C_\varepsilon$ should only be estimated with ensemble averaged quantities from the entire time series for which the statistics are stationary. If $C_\varepsilon$ is to be estimated at each time snap shot it is necessary to correctly account for the time lag that occurs from the large scale energy injection to the fine scale energy dissipation. Even after correctly correlating the energy injection with the energy dissipation, the instantaneous value of $C_\varepsilon$ can vary quite considerably (e.g. $\pm 30\%$) over the extent of the simulation. Such a variation may account for the scatter in magnitude of $C_\varepsilon$ in previously published results. Both the present numerical and experimental results suggest that the asymptotic value for $C_\varepsilon$ is about 0.5. In light of this, the previously held view that the asymptotic value of $C_\varepsilon$ may be dependent on the large scale energy injection could be suspect. Lastly, the results presented are strictly applicable only to isotropic turbulence that is stationary in time. However, it would be interesting to estimate $C_\varepsilon$ for simulations of turbulence unsteady in space and/or time e.g. anisotropic turbulence or anisotropic homogeneous turbulence with a mean shear because there is little known for these flows about how the turbulent kinetic energy is dissipated.
