June 2012 | Volume 3 | Article 200 | www.frontiersin.org

The architecture of secondary lymphoid organs (SLOs) is supported by several non-hematopoietic stromal cells. Currently it is established that two distinct stromal subsets, follicular dendritic cells and fibroblastic reticular cells, play crucial roles in the formation of tissue compartments within SLOs, i.e., the follicle and T zone, respectively. Although stromal cells in the anlagen are essential for SLO development, the relationship between these primordial cells and the subsets in adulthood remains poorly understood. In addition, the roles of stromal cells in the entry of antigens into the compartments through some tissue structures peculiar to SLOs remain unclear. A recently identified stromal subset, marginal reticular cells (MRCs), covers the margin of SLOs that are primarily located in the outer edge of follicles and construct a unique reticulum. MRCs are closely associated with specialized endothelial or epithelial structures for antigen transport. The similarities in marker expression profiles and successive localization during development suggest that MRCs are stromal cells that descend from a specific stromal subset in the anlagen.

INTRODUCTION
Secondary lymphoid organs/tissues (SLOs) are essential for the efficient induction of adaptive immune responses. Several types of SLOs, including the lymph nodes (LNs), spleen, and mucosal-associated lymphoid tissues (MALTs), such as Peyer’s patches (PPs), are strategically positioned throughout various places within the body. SLOs are an elaborate filter that samples antigens and is equipped with highly sensitive immune sensors. In order to collect and filtrate foreign antigens, SLOs contain specialized tissue structures that are associated with the endothelium or epithelium. Immune cells such as lymphocytes, dendritic cells (DCs), and macrophages accumulate to high densities and form compartments. A remarkable feature common to all SLOs is the segregated localization of B cells and T cells. The architecture of SLOs is supported by several types of non-hematopoietic stromal cells of mesenchymal origin, which construct networks and define compartments (Mueller and Germain, 2009; Roozendaal and Mebius, 2011). Stromal networks provide not only a functional foothold but also a space for immune cell activities, as well as a physical framework for the tissue. Moreover, growing evidence indicates that stromal cells also play critical roles in immune cell function and homeostasis (Link et al., 2007; Fletcher et al., 2010; Suzuki et al., 2010; Lukacs-Kornick et al., 2011). SLOs are programmed to develop from the anlagen that occur at certain places and during restricted periods in the fetus and infant. In addition, stromal cells are known to be important for SLO development and maintenance (Mebius, 2003). Here, I focus on a recently identified stromal subset, marginal reticular cells (MRCs), and summarize their characteristics. I also discuss the relationship between MRCs and tissue structure, other stromal subsets, and immunological functions.

T AND B CELL COMPARTMENTS AND TWO CONVENTIONAL STROMAL CELL SUBSETS
As described above, B cells and T cells localize to distinct regions within SLOs. B cells accumulate to form follicles (B zone) in the outer cortex beneath the capsule in LNs or in the outer perifollicular lymphoid sheath (PALS) in the spleen. A cluster of large follicles is the core tissue of PPs. During immune responses, activated B cells in the follicles form germinal centers, where they differentiate into high-affinity antibody producers (Oyster et al., 2000). In contrast, T cells localize to a separate area (T zone) adjacent to the follicles, i.e., the paracortex in LNs, inner PALS in the spleen, or interfollicular region (IFR) in PPs. DCs also accumulate in the T zone to present antigen and prime T cells (Steinman et al., 1997).

There are two different types of mesenchymal stromal subsets in the B and T zones (Figure 1A). Follicular dendritic cells (FDCs) form a dense network in the center of the follicles and have received considerable attention because of their importance in antibody production by B cells (Tew et al., 1997;
A newly identified stromal subset, marginal reticular cells

The outer margin of the LN cortex, just beneath capsule, is surrounded by the subcapsular sinus (SCS; Figure 1A). The luminal surface of the SCS is covered by lymphatic endothelial cells and their cortical side is backed by the basement membrane, called the “floor” (Szakal et al., 1983). Particularly within the IFRs, reticular fibers spread out from the floor into the paracortex (Gretz et al., 1997). Importantly, a thin layer of reticular structure is also observed in the outermost region of the follicles. FRC-like stromal cells in the follicular reticulum express CXCL13 and MAdCAM-1 but not CCL21, which indicates that these cells are distinct from T zone FRCs, while the FDC marker CR1/CD35 was undetected or only weakly expressed in these cells (Katakai et al., 2004a, Figures 1B and 2A). FDCs do not generate reticular fibers, and accordingly, the reticular marker ER-TR7 is virtually absent in the center of the follicles (Katakai et al., 2004a,b). In addition, reticular cells in the subcapsular region specifically express RANKL/TRANCE, which is a TNF-family cytokine that is essential for LN development (Dougal et al., 1999; Kong et al., 1999). Therefore, these stromal cells were thought to be a new stromal subset and were designated marginal reticular cells (MRCs; Katakai et al., 2008). Of note, a substantial amount of CXCL13 is constitutively expressed in MRCs in resting small follicles even if FDCs express undetectable levels of CXCL13 (Figure 1B). It is well established that the outer edge of PALS in the spleen, especially that which lies over the follicles, is bordered by a MAdCAM-1\(^+\)
MRCs AND THE ANTIGEN ENTRY ROUTE IN SLOs

The cells that constitute the lining of basement membrane beneath the marginal sinus (MS) are known as follicular dendritic cells (FDCs). In SLOs, the FAE functions as the barrier in which a specialized epithelial cell called M cells transfers bacteria or particles from the gut lumen to underlying DCs or macrophages (Kraehenbuhl and Neutra, 2000). Therefore, MRCs support the frontline antigen-transporting apparatus in each SLO. The basic design of SLOs is that the follicles are primarily arranged toward the site of antigen entry and are accompanied by T zones. Thus, from a stromal viewpoint, the whole tissue architecture appears to be organized toward the MRC layer.

Although the immunological functions of MRCs remain elusive, it was previously shown that the conduit network constructed by MRCs in the outer follicle transports small soluble antigens to follicular B cells and FDCs (Jabot and Germain, 2009; Rouzendaal et al., 2009). Most CD169+ macrophages are positioned at the cortical side of the SCS floor and protrude an extension into the sinus lumen to capture particles (Phan et al., 2009). Thus, MRCs might be involved in the localization, morphology, and function of these macrophages. M cell development in PPs requires RANKL-RANK signaling, which is likely controlled by a RANKL-expressing MRC network just beneath the FAE (Knoop et al., 2009). Inhibiting the LT pathway, which abolishes MRC signatures in the splenic white pulp, disturbs the MS structure (Koike et al., 1996; Balogh et al., 2007; Katakai et al., 2008; Zindl et al., 2009). Moreover, elevated ICAM-1, VCAM-1, and CXCL13 expression implies that MRCs are involved in the dynamic interstitial migration of follicular B cells as a functional scaffold. CD169+ macrophages have been shown to directly deliver particulate antigens to antigen-specific B cells in this area (Carrasco and Batista, 2007; Phan et al., 2009), suggesting that MRC network-mediated control of B-cell migration may impact this process. Since MRCs are also present in the IFC region, they possibly regulate the transmigration of DCs from the SCS toward the T zone.

MRCs AND ORGANIZER STROMAL CELLS IN SLO DEVELOPMENT

Secondary lymphoid organs develop from the anlagen, which are aggregates of mesenchymal and hematopoietic cells associated with vessels or epithelium, at a defined site and period in the fetus or infant (Mebius, 2003). A critical event in the development of the SLO anlagen is the accumulation of CD45+ CD14+ CD3+ hematopoietic cells, which are also known as lymphoid tissue. The spleen filters blood, in which branches of the central artery open to the MS and marginal zone (MZ), where immune cells survey the blood contents. In these specialized sinus structures, the border barriers are the lymphatic endothelium in the SCS of the LN and the blood endothelium in the MS of the spleen, both of which are supported by the MRC reticulum. Interestingly, CD164+ metallocrophic macrophages are selectively distributed near the sinus lining over the follicles, some of which settle across the endothelial barrier and convey particulate antigens from the sinus lumen into the lymphocyte compartment (Szakal et al., 1983; Taylor et al., 2005; Carrasco and Batista, 2007; Phan et al., 2009). DCs that carry antigens from the tissues via the lymphatic vessels arrive at the SCS and subsequently move into the paracortex across the floor of the interfollicular channel (IFC; Steinman et al., 1997; Katakai et al., 2004b, 2009). Thus, MRCs are present in the outer follicle transports small soluble antigens to follicular B cells and FDCs (Jabot and Germain, 2009; Rouzendaal et al., 2009). Most CD169+ macrophages are positioned at the cortical side of the SCS floor and protrude an extension into the sinus lumen to capture particles (Phan et al., 2009). Thus, MRCs might be involved in the localization, morphology, and function of these macrophages. M cell development in PPs requires RANKL-RANK signaling, which is likely controlled by a RANKL-expressing MRC network just beneath the FAE (Knoop et al., 2009). Inhibiting the LT pathway, which abolishes MRC signatures in the splenic white pulp, disturbs the MS structure (Koike et al., 1996; Balogh et al., 2007; Katakai et al., 2008; Zindl et al., 2009). Moreover, elevated ICAM-1, VCAM-1, and CXCL13 expression implies that MRCs are involved in the dynamic interstitial migration of follicular B cells as a functional scaffold. CD169+ macrophages have been shown to directly deliver particulate antigens to antigen-specific B cells in this area (Carrasco and Batista, 2007; Phan et al., 2009), suggesting that MRC network-mediated control of B-cell migration may impact this process. Since MRCs are also present in the IFC region, they possibly regulate the transmigration of DCs from the SCS toward the T zone.

MRCs AND ORGANIZER STROMAL CELLS IN SLO DEVELOPMENT

Secondary lymphoid organs develop from the anlagen, which are aggregates of mesenchymal and hematopoietic cells associated with vessels or epithelium, at a defined site and period in the fetus or infant (Mebius, 2003). A critical event in the development of the SLO anlagen is the accumulation of CD45+ CD14+ CD3+ hematopoietic cells, which are also known as lymphoid tissue.
inducer (LTi) cells that interact with mesenchymal stromal cells called lymphoid tissue organizer (LTo) cells (Meitus et al., 1997). A TNF family cytokine, lymphotoxin (LT-)β1β2 that is expressed by LTi cells transmits signals to LTo cells via the LT-β receptor. LTi cells subsequently induce the expression of adhesion molecules, including ICAM-1, VCAM-1, and MAdCAM-1, and chemokines CXCL13, CCL19, and CCL21 (Honda et al., 2001; Cupedo et al., 2004a; Bénétreh et al., 2010). In particular, CXCL13 is especially important in attracting LTi cells to the anlagen via its receptor CXCR5 (Finke et al., 2002; Luther et al., 2003; Ohi et al., 2003). It is assumed that a positive feedback loop, i.e. newly immigrating LTi cells that produce LT further activate LTi stromal cells, promoting the organization of the anlagen. As lymphocytes began to accumulate after birth, the tissue expands and the compartments supported by different stromal cell subsets are induced (Cupedo et al., 2004b; Bajenoff and Germain, 2010).

Marginal reticular cells and LTo cells express a very similar pattern of various markers (Figure 2A), suggesting that there is some relationship between these two stromal cells. LTo cells seem to be more concentrated in the marginal region of the LN anlagen adjacent to the lymphatic sinus of the presumptive SCS (Finke et al., 2002; Cupedo et al., 2004a; Béret et al., 2004; Katakai et al., 2008). This LTo cell layer appears to expand outwardly with the growth of the anlagen, which ultimately appears to become the MRC layer (Katakai et al., 2008). Likewise, as lymphocytes accumulate around the central artery in the postnatal spleen, LTo cells expressing MAdCAM-1 and RANKL expand with the layer and become MRCs in the white pulp. These findings strongly suggest that MRCs are a direct descendant of the LTi stroma, which preserve the characteristics of LTo cells at specialized sites within SLOs. Even RAG-deficient mice exhibit a subcapsular MRC layer in atrophic LNs and shrunken periarterial MRC sheathes in the spleen, indicating that MRC development occurs independently of B and T cells and is programmed before their colonization (Katakai et al., 2008). This suggests that the in vivo phenotypes of stromal cell subsets are optimally maintained by the tissue circumstances, which are reversible and not due to terminal differentiation. In addition, inflammatory stimuli induce the abundant proliferation of stromal cells and the dramatic remodeling of SLOs (Katakai et al., 2004a; Chyou et al., 2011). Therefore, although MRCs could be converted to other subsets, conventional stromal subsets might also self-renew and be interchangeable in adult SLOs.

**RELATIONSHIP BETWEEN MRCs AND OTHER STROMAL SUBSETS**

Figure 2B shows the possible genealogy of stromal subsets in SLOs. In the embryo, the primordial mesenchyme that is in close proximity to the vasculature or epithelium is committed to form the anlage core and attracts LTi cells. Nerve cells or other less characterized cells are also involved in the initial process (Vinga-Fernandes et al., 2007; van de Pavert et al., 2009). The accumulation of LTi cells facilitates the maturation of mesenchymal cells into LTo cells, which ultimately facilitates the construction of the basic architecture. Typically, LTo cells tend to concentrate at the periphery of the anlage and expand outward with tissue growth, while stromal cells exhibiting weak or no LTo signatures conversely increase in the inner portions of the anlage. Postnatal colonization of B and T cells leads to compartments with the induction of conventional stromal subsets. If this scheme is correct, it follows that all the stromal subsets in adult SLOs are originally derived from LTo cells. Thus, do MRCs that preserve the characteristics of LTo cells have the ability to differentiate into FDCs or FRCs? MRCs share many signatures with other subsets (Figure 2A), suggesting that this is possible. One speculation is that MRCs function as stromal stem cells that continuously supply all of the stromal subsets throughout adulthood. Although this idea is intriguing, it will require cautious consideration and further validation in the future. Mesenchymal cells are generally highly flexible in nature depending on the surrounding environment, and thus specific features can be easily changed. Extended culturing of stromal cells isolated from LNs results in lost expression for many genes, particularly homeostatic chemokines (Katakai et al., 2004a; Totei et al., 2009). This suggests that the in vivo phenotypes of stromal cell subsets are optimally maintained by the tissue circumstances, which are reversible and not due to terminal differentiation. In addition, inflammatory stimuli induce the robust proliferation of stromal cells and the dramatic remodeling of SLOs (Katakai et al., 2004a; Chyou et al., 2011). Therefore, although MRCs could be converted to other subsets, conventional stromal subsets might also self-renew and be interchangeable in adult SLOs.

**REMODELING OF SLOs AND TERTIARY LYMPHOID STRUCTURES**

During immune responses, stromal structures within SLOs are dramatically remodeled (Gertz et al., 1997; Katakai et al., 2004a). Some infections cause a severe disruption of tissue structures within the LNs and splenic white pulp within a few days, which is restored as the pathogens are eradicated (Mueller et al., 2007a,b; Scandella et al., 2008; St John and Abraham, 2009). This restoration process likely recapitulates a self-organizing process via a feedback reaction similar to SLO development. Importantly, LTi-like cells are also present in adult tissues and regulate infection-associated remodeling of SLOs (Kim et al., 2005; Scandella et al., 2008). Although the role of MRCs in such processes is unknown, they possibly have an organizing role in collaboration with LTi-like cells and determine the outer frame of SLOs during reconstruction.

In chronic inflammation associated with various organ pathologies, large numbers of infiltrating lymphocytes often lead to organizations that are similar to SLOs, known as tertiary lymphoid tissues (TLTs; Drayton et al., 2006). B and T cells are segregated and corresponding networks of stromal cell subsets are induced. It would be interesting to determine whether MRCs are present in these ectopic lymphoid structures; however, MRC-like cells and related tissue structures are not observed in TLTs that developed during mouse autoimmune gastritis (Katakai et al., 2006, 2008). It should be emphasized that TLTs are fundamentally not programmed lymphoid organizations and naturally do not associate with the antigen-transporting structures. Therefore, MRCs are likely absent in TLTs. Even though stromal cells that are phenotypically similar to MRCs might be induced in some lesions, they would not be identified as MRCs unless they closely associate with the specific endothelial or epithelial structure and form a layered reticulum at the outer follicles.
CONCLUSION
Marginal reticular cells are a unique stromal cell subset common to SLNs. MRCs are clearly different from conventional stromal cells that are induced or matured through interactions with lymphocytes after birth, and are directly derived from ELS stromal cells in the anlagen and independent of lymphocytes. The network of MRCs is closely associated with the antigen-transporting cells in the anlagen and independent of lymphocytes. The network of MRCs is closely associated with the antigen-transporting cells in the anlagen and independent of lymphocytes. The network of MRCs is closely associated with the antigen-transporting cells in the anlagen and independent of lymphocytes.
