Abstract

Background: Microalbuminuria is an early lesion during the development of diabetic nephropathy. The loss of high molecular weight proteins in the urine is usually associated with decreased expression of slit diaphragm proteins. Nephrin, is the major component of the glomerular slit diaphragm and loss of nephrin has been well described in rodent models of experimental diabetes as well as in human diabetic nephropathy.

Methodology/Principal Findings: In this manuscript we analyzed the role of PKC-alpha (PKCα) on endocytosis of nephrin in podocytes. We found that treatment of diabetic mice with a PKCα-inhibitor (GO6976) leads to preserved nephrin expression and reduced proteinuria. In vitro, we found that high glucose stimulation would induce PKCα protein expression in murine and human podocytes. We can demonstrate that PKCα mediates nephrin endocytosis in podocytes and that overexpression of PKCα leads to an augmented endocytosis response. After PKC-activation, we demonstrate an inducible association of PKCα, PICK1 and nephrin in podocytes. Moreover, we can demonstrate a strong induction of PKCα in podocytes of patients with diabetic nephropathy.

Conclusions/Significance: We therefore conclude that activation of PKCα is a pathomechanistic key event during the development of diabetic nephropathy. PKCα is involved in reduction of nephrin surface expression and therefore PKCα inhibition might be a novel target molecule for anti-proteinuric therapy.

Introduction

The activation of protein kinase C (PKC) in the kidney is a well known pathway of the diabetic milieu. However the influence and function of PKC on podocyte actions has so far not been studied systematically. The 10 PKC family members are products of distinct genes and differ in their biochemical properties, tissue specific expression and intracellular localization [1]. PKCs are stimulated in response to cytokines as well as various stressors including osmotic stress and high glucose [2]. PKCs can be subclassified into three groups: The conventional isoforms (PKCα, βI, βII and γ) require a lipid cofactor (phosphatidylycerine (PS), Ca2⁺ or 1,2-diacylglycerol (DAG)) for activation; the novel isoforms (PKCδ, ε, η, θ, μ) are Ca2⁺ independent and the atypical isoforms (PKCζ/λ, ϵ) require only PS [3]. With the exception of the atypical PKC-isoform, PKCζ/λ, the isoform-specific knockout does not lead to a distinct renal phenotype; however in conditions with aberrant PKC-activation, such as diabetes or unilateral ureteric obstruction, the role of different PKC-isoforms becomes apparent. We previously described that PKCζ deficient mice show a better outcome after streptozotocin (STZ) induced diabetes with less proteinuria and preserved nephrin expression [5,6]. To study the involvement of PKCα in proteinuria development in diabetic nephropathy, we treated mice after streptozotocin induced diabetes with a synthetic PKCα inhibitor (GO6976), which could prevent proteinuria development and led to preserved nephrin expression. Biochemical analysis in wildtype and PKCα deficient podocyte lines revealed a central role for PKCα in endocytosis of the slit diaphragm component nephrin. This endocytosis mediation could account for the preserved nephrin expression in vivo. Since we observed increased expression of PKCα in podocytes in renal biopsies of patients with diabetic nephropathy we conclude that PKCα inhibition might be a useful therapeutic option to prevent proteinuria development.

Materials and Methods

Ethics Statement

Animal work was conducted according to the guidelines of the American Physiologic Society and was approved by Institutional Animal Care and Use Committee of Hannover Medical School and the animal welfare authorities of lower saxon. All efforts were made to minimize the number of animals used and their suffering. The mice received a standard diet with free access to tap water.

Clinical renal biopsy samples

Renal tissue was obtained from the archives of the Department of Pathology, Hannover Medical School. Paraffin-embedded specimens of normal kidney from nephrectomies performed for tumor, and renal biopsy samples from adults with diabetic nephropathy were included in this study. Renal biopsies were used in accordance with the ethical standards of the Hannover Medical School and with the declaration of Helsinki of 1975, as revised in 1983. All patients consented at hospital admission to experiments on their anonymized archived tissue samples.

Type I diabetes model

Type I diabetes was induced in 8-week-old SV129 male mice obtained from Charles River Laboratories (Sulzfeld, Germany) by intraperitoneal injection of streptozotocin (STZ) (Sigma-Aldrich, St Louis, MO) at 125 mg/kg/day in 50 mmol/l sodium citrate buffer (pH 4.5) on days 1 and 4. The blood glucose level was measured with the Glucometer Elite (Bayer, Leverkusen, Germany) every other day. Approximately 80% of the animals were diabetic 14 days after the first injection. Only animals which have stable blood glucose level more than 15 mmol/l and no loss of weight more than 20% within the first days after onset of diabetes were used for following experiments. The plasma glucose level was measured once weekly. The diabetic mice were distributed into two groups (n = 23 per group). One group of diabetic mice was treated daily with GO6976 (LC Laboratories, Woburn, Massachusetts) in dose 100 μg/8 μl DMSO subcutaneously, the second group was injected daily with 8 μl DMSO alone. Group of nondiabetic mice (n = 16) at 8 weeks of age were assessed for blood glucose and albuminuria and served as controls.

Albuminuria

Animals were placed in metabolic cages for 24-hour urine collection. Albumin concentration in appropriately diluted urine samples was measured using the Albuwell M Assay Kit (Excell, Philadelphia, PA, USA) according to the manufacturer’s instructions.

Statistics

Data are shown as mean ± SD and were compared by Student’s t-test. Data analysis was performed using Excel statistical software. The data for albumin excretion were compared by ANOVA, and the Bonferroni multiple comparison test was used as posttest. Data analysis was performed using InStat. Significant differences were accepted when P<0.05.

Antibodies and Inhibitors

Antibodies that were used for Western blotting, immunohistochemical and immunofluorescence studies were: rabbit anti-PKCζ, rabbit anti-β-tubulin, rabbit anti-PICK1 (Santa Cruz Biotechnology, Santa Cruz, CA), guinea pig polyclonal anti-neprin (for immunohistochemical studies) (PROGEN, Heidelberg, Germany), ectodomain rabbit anti-neprin (for endocytosis assays) (Santa Cruz Biotechnology, Santa Cruz, CA) goat anti-podocalyxin (R&D, Minneapolis, USA), rabbit anti-flag, rabbit anti-myc, rabbit anti-GFP (Cell Signaling Technology, Beverly, MA USA), mouse anti-V5 antibody (Serotec, Kidlington, UK), Alexa Fluor 568 goat anti-guinea pig IgG (Invitrogen, Carlsbad, CA, USA). The used PKC inhibitor was the PKCζ-inhibitor (GO6976) (Calbiochem, Merck, Darmstadt, Germany). Quantitative PCR (Q-PCR) analysis of cultured cells

Total RNA was prepared from cultured human or murine podocytes using the RNeasy®MiniKit (Qiagen, Hilden, Germany) following the protocol recommended by the manufacturer with an additional step of DNase digestion (RNase-Free DNase Set; Qiagen). One microgram of total RNA was reverse transcribed using Oligo (dT) 15 and random primers and M-MLV Reverse Transcriptase (Promega, Mannheim, Germany). Quantitative PCR (qPCR) was performed on a Light Cycler 480 (Roche, Mannheim, Germany). The cDNA was amplified using Fast Start Taq Polymerase (Roche Diagnostics, Mannheim Germany), SYBR Green (Molecular probes, Eugene, OR), gene specific primers and the following PCR conditions: 5 min at 95°C, 45 cycles for 10 s at 95°C, 10 s at 60°C and 10 s at 72°C. Specificity of the amplification product was verified by melting curve analysis. The samples were measured as multiplexed reactions and normalized to the constitutive gene human Hypoxanthin-Phosphoribosyl Transferase 1 (HPRT-1). All primers for the listed transcripts were designed using Primer3 software: mPKCζ left: AGA ACA GGG AGA TCC ACG CA, mPKCζ right: CAA AGT TTT CTG CTC CTT TGC, hPKCζ left: ACC ATT CAA GCC GTT TTT CTG CTC CTT TGC, hPKCζ right: GCC TG TGG CCT CGT GTG TGA AGA, mNephrin left: GGG GAC GCC TCT ATG ATG A, mNephrin right: TGG GTG CTG ATA TTT GAC CTC, hNephrin left: AGG AGC CAT AGG GAA TGG AC, hNephrin right: GCA GAC GGA GCC TTC TTG T.

Isolation of glomeruli, establishment of conditionally immortalized murine podocyte cell lines and podocyte culture

Targeted disruption and generation of PKCζ-deficient homozygous mice on a SV129 background is described elsewhere [7]. PKCζ-deficient mice were crossed to immorto mice (in BL6/C57 background) and used for generation of immortalized cell lines. Isolation of glomeruli and establishment of PKCζ deficient murine podocyte lines was described earlier [8]. Every experimental setup and result was confirmed in 3 different clones of PKCζ+/+ and PKCζ−/− podocytes. Continuous cultivation of conditionally immortalized mouse podocytes was performed as described by Mundel et al. 1996 [9].

Western Blot Analysis

To analyze whole cell protein lysates from cultured podocytes, either untreated or treated cells were lysed on ice in RIPA buffer (50 mM Tris pH 7.5, 150 mM NaCl, 0.5% sodium deoxycholate, 1% Nonidet P-40, 0.1% SDS) containing protease inhibitor (Complete mini, Roche, Mannheim, Germany), 1 mM sodium orthovanadate, 50 mM NaF and 200 μg/l okadaic acid. Lysates were centrifuged at 12,000 rpm and aliquots of the supernatants were separated by 10% SDS-PAGE and transferred to PVDF membrane (Immobilon-P, Millipore, Bedford, MA, USA). After probing with primary antibodies antigen-antibody complexes were detected with horseradish peroxidase-labeled anti-rabbit and anti-mouse antibodies, respectively, and visualized using enhanced chemiluminescence reagents (Pierce, Rockford, IL, USA) according to the manufacturer’s protocol.

Laser microdissection of paraffin embedded tissue, mRNA extraction and Q-PCR

Formalin fixed and paraffin embedded renal biopsies were cut into 4-μm sections. 60 glomeruli of each specimen (n = 5 controls and n = 5 with DN) were micro dissected on a mmi CellCut Plus System (Olympus, Hamburg, Germany) without prior deparaflin-
nization and collected for RNA isolation. The tissue was digested in 50 μL of 20 mg/mL Proteinase K solution (Merck, Darmstadt, Germany), 50 μL of RNA digestion solution (4.2 M guanidinium thiocyanate, 30 mM Tris-HCl of pH 7.6, and 2% sodium N-lauroylsarcosine), and 0.5 μL of 2-mercaptoethanol at 55°C over night immediately. Then 10 μL of 3 M sodium acetate (pH 5.2), 65 μL of Roti-Aqua-Phenol (Roth, Karlsruhe, Germany), and 27 μL of chloroform were added to precipitate RNA. After phase separation through centrifugation, the aqueous phase (95 μL) was carefully removed and added to 96 μL of 2-propanol and 1 μL of glycogen (20 mg/mL; Roche, Mannheim, Germany) as precipitation carrier. The precipitated RNA was then stored at −20°C. cDNA synthesis was performed for 2 hours at 37°C as prescribed in the kit manual of the High Capacity cDNA Reverse Transcription Kit (Applied Biosystems, Massachusetts, USA). cDNA was then pre-amplified using TaqMan® PreAmp Master Mix (2×) (Applied Biosystems, Massachusetts, USA) according to the manual of the manufacturer. Primer pool used for pre-amplification consisted of 6 TaqMan® Assays (Applied Biosystems, Massachusetts, USA), including PKC-alpha, WT1 and two housekeeping genes (β-Gus, and Polymerase R2A). 25 μL of TaqMan® PreAmp Master Mix as well as 12.5 μL of the assay pool were added to 12.5 μL of cDNA and subjected to the following thermocycler program: 95°C for 10 minutes, 14 cycles of 95°C for 15 seconds and 60°C for 4 minutes. Pre-amplified cDNA was stored at −20°C. 5 μL of the pre-amplified cDNA (1:10 dilution) were added to 15 μL of master mix consisting of 10 μL of Gene Expression Master Mix (Applied Biosystems, Massachusetts, USA), 4 μL of purified water and 1 μL of the respective TaqMan® Gene Expression Assay (Applied Biosystems, Massachusetts, USA). RT-PCR primers were used to amplify PKC-alpha (Hs00176973_m1), WT1 (Hs 01103751_m1), POLR2A (Hs 00172187_m1) and GUS B (Hs 99999908_m1). RT-PCR was performed with a 7500 Fast Real-Time PCR System (Applied Biosystems, Massachusetts, USA). Results are given as relative expression levels.

Transfection

The day before transfection HEK 293T cells were seeded on 24-well plates for endocytosis assays or on 10 cm-dishes for immunoprecipitation assay. Cells were transfected using Fugene HD transfection reagent (Roche Diagnostics, Mannheim, Germany) according to the manufacturer’s protocol. After transfection cells were cultured in normal growth medium for 48 h.

Immunoprecipitation

HEK 293T cells were transfected like mentioned above. Then the cells were washed carefully with ice-cold PBS on ice. For lysis 900 μL RIPA buffer were added to the cells. The lysate was incubated for 15 min on ice and centrifuged at 14,000 rpm for 15 min at 4°C. 50 μL Flag-beads (50% slurry in Triton buffer) (Sigma, St. Louis, USA) were added to the supernatant and rotated overnight at 4°C for 1 h (up to overnight). After that the beads were centrifuged at 3000 rpm for 1 min at 4°C and washed with RIPA-buffer 5 times. Proteins were eluted by boiling the beads in Laemmli buffer. Lysates and eluates are analyzed by SDS polyacrylamide gel electrophoresis.

Immunocytofluorescence-based Endocytosis Assay

For internalization studies, cells were plated in 24-wells on glass slides and differentiated for 10 days. Cells were cooled down at 4°C and incubated with the raft-mediated endocytosis marker Cholera toxin subunit B (Alexa Fluor 488 conjugated) (Invitrogen, Eugene, Oregon, USA) and simultaneously with an ectodomain anti-nephrin antibody and Cy3-conjugated secondary antibody for 1 h in RPMI without FCS at 4°C. After three washes with PBS cells were incubated for 20 min at 4°C or 37°C to induce internalization before fixing them with 4% paraformaldehyde. The pictures were taken with an Inverted-2 Confocal Microscope and Leica Application Suite Software (Leica, Bonn, Germany). Post processing was done with Photo Shop 6.0.

ELISA-based Endocytosis Assay

HEK 293T cells were transfected with constructs (mNephrin+flag, hNephrin-SV5, pGFP-N1, PKCα-GFP) using the FUGENE-Reagent (Roche, Mannheim, Germany). 24-well plate was coated with poly-L-lysine 1:1 diluted with H2O (Sigma P4707 0,01% Solution, Steinheim, Germany) and incubated overnight at 37°C. The next day the plate was washed once with PBS and transfected HEK-293T cells (6×10^5 /well) were seeded. About 30 hours after the transfection cells were cooled on ice for 10–15 minutes. The medium was replaced with DFH-medium (1% FCS and 20 mM HEPES in RPMI1640) containing 1:750 mouse anti-V5 antibody or 1:200 rabbit anti-flag antibody. The cells were incubated for 30–60 minutes at 4°C and then washed three times with cold DFH-medium (1% FCS and 25 mM HEPES in RPMI1640). To induce internalization cells were incubated with warm DFH-medium (1%FCS and 5 mM HEPES in RPMI1640) for 20 minutes at 37°C. The cells were fixed with 3,7% PFA for 15 minutes, washed twice with PBS and kept over night at 4°C. For blocking 2% normal goat serum (Jackson ImmunoResearch, USA) with 0.5% Tween-20 in PBS was used for at least 30 minutes. After washing once with PBS the cells were incubated in RPMI1640-medium with alkaline phosphatase coupled anti-mouse or anti-rabbit antibody (dilution 1:7.500) for 1 hour and washed three times with PBS, each wash 5–10 minutes. The cells were then incubated with p-Nitrophenyl Phosphate (pNPP; Sigma N2765, Steinheim, Germany, one tablet was re suspended in 20 ml 0.1 M glycine, 1 mM MgCl2, 1 mM ZnCl2, pH 10.4) for about 1 hour at 37°C or until the solution turned yellow. One aliquot, about 100 μL from the reaction was transferred in a 96-well-plate and the extinction was measured at 405 nm in a microplate reader. Murine PKCα+/+ and PKCα−/− and human podocytes were differentiated for 10 days. Endocytosis of endogenous nephrin was induced by temperature shift (20 min) or by stimulation with high Glucose medium (30 mM). For high glucose treatment cells were cultured for 1 hour with medium containing 30 mM D-glucose or with medium containing normal glucose concentration supplemented with Mannitol as osmotic control. The cells were cooled down at 4°C to stop endocytosis and nephrin was labeled with an ectodomain anti-nephrin antibody. Endocytosis of nephrin was measured by the same method as mentioned above.

Immunohistochemistry

After dissection, kidneys were washed with phosphate-buffered saline and immediately frozen in tissue molds containing OCT compound (Tissue Tek). For fluorescent images were collected onto slides, blocked with 10% donkey-serum, stained with the appropriate primary antibody followed by a Cy3-Jackson antibody /ml IP-Volume and sepharose-A beads in IP-buffer (25 mM Tris-HCL, pH 7.5, 1 mM DTT, 30 mM MgCl2, 40 mM NaCl, 0.5% NP-40 and protease inhibitors) overnight at 4°C. The pellets were washed in IP-buffer (three washing steps in total). The protein was eluted by boiling the beads in Laemmli buffer. Lysates and eluates are analyzed by SDS polyacrylamide gel electrophoresis.
Results

PKCζ is upregulated in podocytes in experimental as well as in human diabetic nephropathy

First, we wanted to examine whether diabetes leads to changes in PKCζ expression in mice and in patients with diabetic nephropathy. When we stained frozen kidney cortex sections of control mice and mice 4 weeks after STZ-induced diabetes, we found a strong upregulation of glomerular PKCζ expression (Fig. 1A). Next to a strong upregulation in the endocapillary/mesangial compartment, double stainings with the podocyte marker podocalyxin revealed a strong upregulation in podocytes in the diabetic mice (Fig. 1A). Similarly, when we stained different biopsy samples from patients with features of diabetic nephropathy (n = 10) compared to healthy controls (n = 7), we found that PKCζ staining in healthy controls is predominantly visible in the glomerular endothelium (Fig. 1B, panel a, b), whereas podocyte staining was absent. Strikingly, in patients with diabetic nephropathy we can demonstrate an expression of PKCζ in glomerular endothelium as well as strong expression in all podocytes (Fig. 1B, panels c,d). This clear difference was detectable in all 10 examined patients. All podocytes displayed a strong PKCζ staining, whereas in all examined control glomeruli endothelial staining was evident, but podocytes were rarely detected positive for PKCζ. When all glomeruli were semiquantitatively scored with a score of 1 indicating absent or moderate expression and a score of 2 indicating strong expression we could document uniformly an average score of 1 for all examined control glomeruli and an average score of 2 for all examined diabetic glomeruli (Fig.1B, panel c). In addition, when we performed laser capture microscopy and extracted mRNA from control and diabetic human glomeruli we found a significantly increased mRNA expression of PKCζ mRNA in the diabetic glomeruli (Fig. 1B, panel f, *p<0.05). To delineate that high concentration of D-glucose (30 mM) would lead to podocytic upregulation of PKCζ, we cultured murine and human podocytes for up to 24 hours in the presence of 30 mM D-glucose. We found a significantly upregulated expression of podocytic PKCζ on mRNA and protein level. In contrast, mannitol had no significant effect on PKCζ expression (Fig. 2, panel a, b). These data indicate, that PKCζ expression is upregulated in podocytes in experimental diabetes in mice as well as in human diabetic nephropathy. Moreover, we found in vitro that high glucose is a strong regulator of PKCζ expression in podocytes. To exclude direct expression effects on nephrin mRNA in murine and human podocytes we performed Q-PCR-analysis of nephrin mRNA in both cell types during the 24 hour time course. We could not detect a transcriptional regulation of nephrin mRNA in both cell types in the presence of 30 mM glucose or mannitol (Supplementary Fig. S1).

Chemical PKCζ inhibition stabilizes nephrin expression and prevents proteinuria in streptozotocin induced diabetes in mice

Since we had previously described preserved nephrin expression and reduced proteinuria in diabetic PKCζ deficient mice we wanted to test whether chemical inhibition of PKCζ would have a similar protective effect. Our first observation was that under diabetic conditions the glomerular expression of nephrin is downregulated. Strikingly, the treatment of diabetic mice with the PKCζ inhibitor GO6976 led to preserved nephrin expression (Fig. 3A). When we compared total protein excretion in diabetic mice untreated or treated with GO6976 for four weeks, we found a significant reduction of urinary protein levels in the GO6976 treated group (67±9.7 µg/24 h, n = 23) compared to untreated diabetic mice (234±240.3/24 h, n = 23, *p<0.05) (Fig. 3B). This treatment success led us to the hypothesis, that inhibition of PKCζ would have a direct effect on nephrin expression and slit diaphragm integrity in vivo and thus it could be of potential use in proteinuric situations.

PKCζ regulates nephrin endocytosis

Since our results so far indicated a direct protective effect of PKCζ inhibition on nephrin expression and proteinuria development we wanted to delineate the underlying mechanisms. Nephrin is a key component of the glomerular slit diaphragm. It is a transmembrane protein (185–200 kDa) with a short intracellular domain, and an extracellular domain with eight distal IgG-like motifs. Nephrin molecules of neighbouring foot processes build a zipper-like structure that makes up the last barrier for serum proteins to the urine [10]. In addition, nephrin is a platform of signaling proteins important for the integrity of the podocyte cytoskeleton and for the activation of signaling cascades such as PI3K/AKT and ERK1/2 that control survival pathways of the podocyte [11]. Mutations of the nephrin gene lead to congenital nephrotic syndrome with proteinuria and renal failure [12]. Thus far, only little is known about the normal protein turnover of slit diaphragm proteins. Recently, Quack et al. described a β-arrestin mediated mechanism of nephrin endocytosis as a molecular basis for the turnover of slit diaphragm molecules [13]. Moreover, Qian et al. demonstrated that nephrin can be internalized via raft-mediated endocytosis [14]. PKCζ has been previously described to regulate caveolar endocytosis [15],[16] and to be involved in endocytosis of transmembrane receptors [17], [18]. On the basis of the published evidence and our results it was tempting to speculate that PKCζ could be a signaling mediator to orchestrate nephrin endocytosis in podocytes. Therefore, we performed an immuno-fluorescence-based endocytosis assay in murine PKCζ-wildtype (PKCζ+/+) and PKCζ-knockout (PKCζ−/−) podocytes in culture. When we examined endocytosis of surface expressed nephrin we could demonstrate that nephrin is endocytosed in PKCζ+/+ podocytes after 20 min temperature shift to 37°C. Nephrin became sorted into larger vesicles and distributed from the cell periphery to the perinuclear compartment. Furthermore, nephrin colocalized with the raft/caveolar-mediated endocytosis marker Cholera toxin B (Fig. 4A, panel b). In contrast to that, we could demonstrate that nephrin endocytosis is almost absent in PKCζ+/+ podocytes in the presence of the PKCζ inhibitor GO6976 and in PKCζ−/− podocytes (Fig. 4A, panels c and e). The general uptake of Cholera toxin B is not inhibited by...
Figure 1. Glomerular PKCα is upregulated in mice and patients with diabetic nephropathy. (A) Immunofluorescence using an anti-PKCα (green) and anti-podocalyxin (red) antibody on frozen kidney cortex sections of control and diabetic mice. White arrowheads in the merged panel depict colocalization of PKCα with podocalyxin. Picture is representative for the majority of glomeruli in control and diabetic mice (n = 5) in each group). (B) Immunohistochemistry using an anti-PKCα antibody shows expression of PKCα in human biopsy samples of healthy control individual (a, b) and a patient with diabetic nephropathy (c, d). Black arrowheads depict expression of PKCα in the glomerular endothelium and open arrowheads depict podocytes in normal and diabetic individual (panel b, d). Bar graphs (e) summarize semiquantitative score of all glomeruli (n = 74 for patients with DN and n = 150 for control cases), indicating 1 for absent or moderate or 2 for strong expression of PKCα in podocytes and mRNA expression of PKCα isolated from control (n = 200) and diabetic (n = 298) human glomeruli in relation to Wt-1 mRNA expression, *p<0.05 compared by Student’s t-test (f). doi:10.1371/journal.pone.0010185.g001
inhibition of PKC\(\alpha\) since intracellular accumulation of green vesicles as indicated by Cholera toxin B uptake in the presence of GO\(\delta\)976 or in the absence of PKC\(\alpha\) is clearly visible (Fig. 4A, panel c and e). This would indicate a partially specific effect for nephrin endocytosis, however a similar effect on other transmembrane proteins cannot be excluded. To exclude non-specific surface binding or uptake of secondary antibody we performed the temperature shift in the absence of primary antibody and we could not detect a significant red fluorescence signal (Supplementary Fig. S2). So in summary, our Cholera toxin B experiments indicate a PKC\(\alpha\) mediated effect on nephrin endocytosis, however for a clear differentiation of raft- or clathrin-mediated endocytosis additional experiments would be required since Cholera toxin B cannot clearly differentiate both endocytosis types.

Figure 2. PKC\(\alpha\) expression is upregulated by high glucose in murine and human podocytes. Quantitative PCR (a) and Western blot analysis (b) for PKC\(\alpha\) in murine and human podocytes depicts induction of protein in a time course experiment after stimulation with high glucose (30 mM) and mannitol as osmotic control for up to 24 hrs (results are representative for 3 independent experiments). Scale bars of quantitative PCR summarizes means of high glucose (white bars) and Mannitol (black bars) of \(n=3\) independent experiments. (*\(p<0.01\), 0 versus 4, 8 hrs (murine) and *\(p<0.05\) 0 versus 0.5, 1, 2 hrs (human) compared by Student’s t-test. Densitometric analysis summarizes means of PKC\(\alpha\) and \(\beta\)-tubulin ratios after high glucose (white bars) and mannitol (black bars) stimulation in \(n=3\) independent experiments. OD was quantified using Quantity One software. *\(p<0.03\), 0 hrs versus 4, 8, 24 hrs (murine), *\(p<0.04\) 0 versus 0.5, 1, 2 hrs (human) compared by Student’s t-test.

doi:10.1371/journal.pone.0010185.g002
To quantify nephrin endocytosis we used an observer independent assay system with a cell-based ELISA. We could demonstrate a reduced rate of nephrin endocytosis in cultured murine PKC\(\alpha\)^+/- and human podocytes in the presence of GO\(\beta\)6976 and in murine PKC\(\alpha\)-/- podocytes after temperature shift to 37°C (Fig. 4B). Furthermore, high glucose treatment for 1 hour leads to endocytosis of nephrin in murine PKC\(\alpha\)^+/- and human podocytes. This effect is significantly higher compared to high glucose treated PKC\(\alpha\)^+/- and human podocytes in the presence of GO6976 and in PKC\(\alpha\)-/- podocytes (Fig. 4C). To test whether PKC\(\alpha\) overexpression would lead to an increased rate of nephrin endocytosis we performed overexpression experiments in HEK293T cells. In this artificial overexpression system we could also document reduced endocytosis of overexpressed mouse and human nephrin constructs in the presence of GO6976. Interestingly, we found that the simultaneous overexpression of a PKC\(\alpha\)-construct would lead to an enhanced nephrin endocytosis response. This effect was partially inhibited in the presence of the PKC\(\alpha\) inhibitor (Fig. 4D). In addition, we could confirm these results in PKC\(\alpha\)^+/- and PKC\(\alpha\)-/- podocytes using surface

Figure 3. PKC\(\alpha\) inhibition or deficiency preserves nephrin expression and reduces proteinuria in vivo. (A) Diabetes was induced in SV129 mice with STZ. Immunofluorescent images show expression of nephrin (red) in control, untreated diabetic or GO\(\beta\)6976 treated diabetic mice (pictures are representative for the majority of glomeruli in the three different groups) (scale bar upper panels 100 \(\mu\)m, lower panels 20 \(\mu\)m). (B) Graphical summary of urinary albumin excretion in 24 hrs of control (n = 16), diabetic (n = 23) and diabetic mice treated with GO\(\beta\)6976 (n = 23), \(*p<0.03\) diabetic mice versus GO\(\beta\)6976 treated diabetic mice.
doi:10.1371/journal.pone.0010185.g003
biotinylation before and after nephrin endocytosis. We again detected a higher amount of biotinylated nephrin in PKCα+/+ podocytes indicating a higher rate of endocytosis in the wildtype cells (Fig. 4E). To exclude non specific surface binding of the primary antibody we performed the experiments with a mouse or rabbit IgG control (Santa Cruz, CA, USA). To ensure that our results in the different cell types were not influenced by reduced cell survival during the temperature shift or transfection procedures we used trypan blue stainings on all cell types to proof cell viability. None of the temperature conditions would affect cell viability in the murine and human podocyte cell lines or the transfected HEK293T cells (Supplementary Fig. S3).

PKCα regulates nephrin endocytosis via PICK1
To understand the observation of reduced proteinuria and preserved nephrin expression mechanistically, we investigated whether PKCα interacts with nephrin and whether that interaction
would lead to nephrin internalization. Using co-immunoprecipita-
tions we could demonstrate a PMA inducible interaction of PKCα and
murine nephrin in transfected HEK293T cells (Fig. 5A). PKCα
binds to nephrin and we detected a strong inducible interaction
within 15 minutes. A similar result was obtained when we used
time! human nephrin in our experiments (Supplementary Fig. S4). Since
PKCα dependent endocytosis has been described earlier in
orchestration with the PDZ- and BAR-domain-containing protein
PICK1 (protein interacting with C-kinase) [19,20], we wanted to
test whether PMA stimulation would lead to recruitment of PICK1
to this complex. Similarly to our results with PKCα, we could
detect a PMA inducible interaction of nephrin and PICK1 (Fig. 5A).
To confirm our results on an endogenous level, we performed co-
immunoprecipitations of endogenous nephrin and endogenous
PKCα in podocytes. Similarly to our results in HEK293T cells, we
found an inducible interaction of PKCα and PICK1 within 15
minutes after stimulation with PMA (Fig. 5B) in PKCα+/+ podocytes. In contrast, no association was detectable in the
PKCα−/− podocytes indicating an endogenous protein complex
specifically orchestrated via PKCα (Fig. 5B). In summary, our data
indicate that PKCα expression can be regulated by different
stressors in podocytes in vitro and in vivo. Specifically in the diabetic
milieu PKCα mediates nephrin endocytosis and PKCα-deficiency
or inhibition leads to preserved nephrin expression on the podocyte
surface and thus has a direct protective effect on the integrity of the
slit diaphragm.

Figure 5. Inducible interaction of transiently overexpressed and endogenous nephrin with PKCα and PICK1. (A) HEKT293T cells were
transiently transfected with mNephrin-flag, PKCα-GFP and PICK1-myc and stimulated with PMA for 0, 5 and 15 min. Nephrin-flag was precipitated
with agarose labelled with an anti-Flag-antibody. The probes were blotted and analyzed for GFP and Myc. (B) Endogenous nephrin and PICK1 were
precipitated (IP) using an anti-nephrin and anti-PICK1 antibody from whole cell lysates of PKCα+/+ and PKCα−/− podocytes which were treated for
0, 5 and 15 min with PMA. The probes were blotted and analyzed for PKCα, nephrin and PICK1.

Discussion

Our results provide novel mechanistic insights into the relationship of PKCζ activity and the signaling response of podocytes under diabetic conditions. Nephrin is a single transmembrane receptor that belongs to a family of adhesion molecules. A genetic defect in nephrin expression leads to congenital nephrotic syndrome [21]; [22]. Furthermore, nephrin signaling contributes to the overall survival response in podocytes and anchors important signaling molecules to the glomerular filtration slit [11]. Nephrin molecules of neighboring foot processes built the backbone of the slit diaphragm and together with the recently identified Nep1 it forms a hetero-oligomeric complex in the plane of the membrane that interacts across the foot process interaction [23], [24]. Since the blood flow dependent changes of the glomerular capillary diameter require constant adaptation processes, it seems likely that foot process formation and the formation of the slit diaphragm is a highly dynamic process with constant turnover and renewal of these transmembrane proteins. A molecular regulation of the slit diaphragm complex turnover via nephrin phosphorylation and endocytosis was first described by Quack and coworkers [13]. In this manuscript we describe PKCζ as a high glucose inducible kinase that orchestrates nephrin internalization in podocytes. We found a significant induction of glomerular PKCζ expression in diabetic glomeruli in podocytes in mice and humans. This stress induced glomerular induction effect in diabetes is novel. A regulation of PKCζ/β in podocytes has previously only been documented in human membranous nephropathy, however the conclusion of its functional role remained elusive [25]. Strikingly, when we injected mice with a PKCζ inhibitor we observed a preserved nephrin expression which is reflected in the urine by a significantly reduced excretion of albumin. This is in line with previous observation from our group where we detected preserved nephrin expression and reduced proteinuria in diabetic PKCζ deficient mice [5]. In addition, we can demonstrate a glucose dependent induction of PKCζ mRNA and protein in murine and human podocytes. Moreover, we demonstrate in different in vitro experiments PKCζ-mediated endocytosis of murine and human nephrin. Quack and coworkers showed a raft-mediated endocytosis of nephrin [14] This is in line with our observations where we can demonstrate that PKCζ-mediated endocytosis of nephrin is raft-mediated. Many other studies showed that raft-mediated endocytosis by caveolar are PKCζ-regulated [15],[16]. Supporting evidence comes from our immunoprecipitation findings, where we demonstrate that PKCζ associates with nephrin and PICK1 after PMA stimulation. Recruitment of PICK1 has been demonstrated as a key step in PKCζ mediated trafficking of AMPA receptors via direct interaction with PKCζ and the AMPA receptor subunits GluR1-GluR4 [19] in the PDZ domain of PICK1. This association is required for AMPA-receptor trafficking. This inducible interaction of endogenous nephrin and endogenous PKCζ is reproducible in transient assays as well as with endogenous proteins in podocytes. On the background of these results we speculate that PKCζ activity contributes to the pathogenesis of proteinuria by disrupting the glomerular filter in response to high glucose via nephrin internalization. Absence or inhibition of PKCζ leads to stabilized surface expression of nephrin and this has positive effects on proteinuria development. We would further hypothesize that nephrin or possibly turnover of the whole slit diaphragm complex is regulated similar as turnover and trafficking of activated growth factor receptors [13]. This would support the role for nephrin as a structural sensor regulating the integrity of the slit diaphragm.

In diabetes microalbuminuria is one of the earliest detectable abnormalities that, when left untreated, will eventually progress to gross proteinuria. Since the degree of proteinuria correlates with tubular interstitial fibrosis the early treatment of proteinuria and prevention of progression to significant proteinuria levels is an important step to delay disease progression. In the development of diabetic glomerulopathy an increase in podocyte foot process width and podocyte loss has been observed in a variety of patients with diabetes [26,27]. Also, loss and downregulation of nephrin is a well described effect in patients with diabetic nephropathy compared to healthy controls [28].

In summary, our results open new avenues for further investigations on slit diaphragm turnover under physiological and pathological conditions. Furthermore, PKCζ inhibition is a promising target molecule for podocyte protective therapy in proteinuric kidney diseases and in particular for diabetic nephropathy.

Supporting Information

Figure S1  Podocytic nephrin mRNA expression is not altered by high glucose treatment. Q-PCR for Nephrin in murine and human podocytes demonstrates mRNA expression in a time course experiment after stimulation with high glucose (30 mM) and mannitol as osmotic control for up to 24 hrs (results are representative for 3 independent experiments).

Figure S3  Podocytes and transfected HEK 293T cells are viable during endocytosis assay. PKCζ+/+, PKCζ−/−, human podocytes and transfected HEK293T cells (hNephrin-SV5 and PKCζ-GFP) were cooled down at 4°C, shifted to 37°C in the absence or presence of the PKCζ inhibitor G06976 or permeabilized with 80% methanol as control for 10 min. Cells were stained with 0,4% trypan blue.

Figure S4  Inducible Interaction of transiently overexpressed human nephrin with human PKCζ. HEK293T cells were transiently transfected with hNephrin-flag and hPKCζ-GFP and stimulated with PMA for 0, 5 and 15 min. Nephrin-flag was precipitated with agose labelled with an anti-Flag-antibody. The probes were blotted and analyzed for GFP and Flag content.
