ABSTRACT

In a previous paper we simulated the orbital evolution of dust particles from the Jupiter Trojan asteroids ejected by the impacts of interplanetary particles, and evaluated their overall configuration in the form of dust arcs. Here we compare the orbital properties of these Trojan dust particles and the Trojan asteroids. Both Trojan asteroids and most of the dust particles are trapped in the Jupiter 1:1 resonance. However, for dust particles, this resonance is modiﬁed because of the presence of solar radiation pressure, which reduces the peak value of the semi-major axis distribution. We ﬁnd also that some particles can be trapped in the Saturn 1:1 resonance and higher order resonances with Jupiter. The distributions of the eccentricity, the longitude of pericenter, and the inclination for Trojans and the dust are compared. For the Trojan asteroids, the peak in the longitude of pericenter distribution is about 60 degrees larger than the longitude of pericenter of Jupiter; in contrast, for Trojan dust this difference is smaller than 60 degrees, and it decreases with decreasing grain size. For the Trojan asteroids and most of the Trojan dust, the Tisserand parameter is distributed in the range of two to three.

Key words. meteorites, meteors, meteoroids – planets and satellites: rings – minor planets, asteroids: general – zodiacal dust – celestial mechanics – solar wind

1. Introduction

Dust ejecta are generated when hypervelocity interplanetary micrometeoroids impact the surfaces of atmosphereless bodies (Krüger et al. 1999; Horányi et al. 2015; Szalay & Horányi 2016). As of July 2016, there are about 4266 known Jupiter Trojan asteroids in the L4 swarm and 2341 in the L5 swarm (JPL Small-Body Database Search Engine). In previous work, we estimated the total cross section of the Trojan asteroids that is exposed to the interplanetary ﬂux, and evaluated the production rate of ejecta particles from the Trojan asteroids (Liu & Schmidt 2018). We also simulated the subsequent evolution of these ejecta particles after ejection, and derived their steady-state spatial conﬁguration.

The orbital parameter distribution of the Trojan asteroids has received considerable interest (Jewitt et al. 2000; Yoshida & Nakamura 2005). The motion of the Trojan dust particles is inﬂuenced by non-gravitational perturbation forces (see Sect. 2) so that their dynamics differs from that of the Trojan asteroids, which is reﬂected in their respective orbital properties. In this paper, we compare the orbital properties of the Jupiter Trojan asteroids and Trojan dust, which show a similar orbital behavior, but are also different in many aspects.

Because of their low number density, there is no detection yet of Trojan dust particles although upper limits on their cross section were inferred (Kuchner et al. 2000), and our work is based on numerical and analytical investigations. The Lucy spacecraft developed by NASA will be the ﬁrst mission to conduct reconnaissance of Jupiter’s L4 and L5 Trojan asteroids (Levison et al. 2017). Because the dust particles are samples from the asteroid surfaces their in-situ compositional analysis by future space missions will allow researchers to directly determine the chemical composition of the asteroids (Sternovsky et al. 2017; Toyota et al. 2017).

2. Brief description of the dynamical model

In this paper, the orbital parameters are deﬁned with respect to the Jupiter orbital inertial frame Oxoyoi. The zoi axis points to the normal of Jupiter’s orbital plane at J2000 epoch, the xo axis is taken to be the intersection of Jupiter’s orbital plane with Jupiter’s equator plane at J2000 epoch, and the yoi axis follows the right-hand rule. The Trojans’ orbital elements in the J2000 ecliptic reference frame are obtained from the JPL Small-Body Database Search Engine, and then are transformed to the frame Oxoyoi.

For the dust particles we analyze simulation results from a previous study (Liu & Schmidt 2018). Here we brieﬂy describe our model. Compared with asteroids, dust particles are subject to non-gravitational forces including solar radiation pressure, Poynting–Robertson (P–R) drag, solar wind drag, and the Lorentz force due to the interplanetary magnetic ﬁeld. We adopt silicate as the material for Trojan dust. In our simulations, particles in the size range [0.5, 32] µm are included. For each size, 100 particles from L4 Trojans are simulated until they hit Jupiter or their Jovicentric distances lie outside the region of interest, [0.5, 15] au. For the details of the dynamical model and numerical simulations, the readers are referred to Liu & Schmidt (2018) and Liu et al. (2016).

3. Distribution of semi-major axis a and orbital resonances

We start our analysis from the distribution of the semi-major axis for L4 Trojans and Trojan dust (Fig. 1). As expected, the distribution of the Trojans’ semi-major axes peaks around aJupiter (5.2 au), while the peak for the dust population is smaller and much wider. This is mainly because of the effect of solar
radiation pressure combined with the Jupiter 1:1 mean motion resonance.

The direction of solar radiation pressure is opposite to that of the solar gravitational force. Thus, the effect of solar radiation pressure can be included in terms of the effective solar mass \( M_{\text{eff}} = M_{\text{Sun}}(1 - \beta) \) (Kresák 1976), where \( M_{\text{Sun}} \) is the mass of the Sun. Other symbols with subscript “eff” in the text are defined when the effective solar mass \( M_{\text{eff}} \) is considered. For grain sizes \(<2 \mu m\), the Trojan particles have short lifetimes (Liu & Schmidt 2018) because the strong solar radiation pressure rapidly expels them away from the \( L_4 \) region. Larger grains \( >4 \mu m \) can be trapped in the 1:1 resonance with Jupiter for a long time. The effective resonant argument \( \Psi_{1:1} \) of the particle’s 1:1 resonance with Jupiter is expressed as

\[
\Psi_{1:1} = \lambda_{\text{eff}} - \lambda_{\text{Jupiter}},
\]

where \( \lambda \) is the mean longitude. At resonance, \( \Psi_{1:1} = 0 \) (Murray & Dermott 1999), and the effective semi-major axis at the Jupiter 1:1 resonance is obtained as (Liou & Zook 1995; Liou et al. 1995)

\[
a_{\text{eff}, 1:1} = a_{\text{Jupiter}} \frac{M_{\text{Sun}}(1 - \beta)}{M_{\text{Sun}} + M_{\text{Jupiter}}}^{1/3}.
\]

Here \( M_{\text{Jupiter}} \) is the mass of Jupiter, and \( \beta \) is the ratio of solar radiation pressure relative to solar gravitational force (Burns et al. 1979). The value of \( \beta \) is size-dependent, the dependence of which on grain size for silicate particles can be found in Fig. 4b of Liu & Schmidt (2018). Kresák (1976) derived the relation between the effective and conventional semi-major axis when dust particles are released at the perihelion and aphelion of a comet. Because of the small eccentricity for the majority of dust particles, this relation can be simplified by neglecting the effect of eccentricity as

\[
a_{\text{eff}} = a_{\text{Jupiter}} \frac{1 - \beta}{1 - 2\beta}.
\]

Combining Eqs. (2) and (3), the conventional semi-major axis at the Jupiter 1:1 resonance is calculated as

\[
a_{1:1} = a_{\text{Jupiter}} \frac{1 - 2\beta}{1 - \beta} \left( \frac{M_{\text{Sun}}(1 - \beta)}{M_{\text{Sun}} + M_{\text{Jupiter}}} \right)^{1/3}.
\]

It is apparent that \( a_{1:1} < a_{\text{Jupiter}} \), and \( a_{1:1} \) becomes smaller with decreasing grain size because their \( \beta \) becomes larger. It follows that solar radiation pressure can efficiently decrease the values of semi-major axes. This explains why the peak in dust density is shifted radially inward from Jupiter (Fig. 7a of Liu & Schmidt 2018). As an example, Fig. 2 shows the evolution of the semi-major axis and resonant argument for an 8 \( \mu m \) particle for 1000 yr. The dust semi-major axis librates around \( a_{1:1} \) with nearly constant amplitude. The resonant argument \( \Psi_{1:1} = \lambda_{\text{eff}} - \lambda_{\text{Jupiter}} \) librates around a fixed angle larger than 60° (Fig. 2a and b). The small wiggles in Fig. 2a and c are also induced by solar radiation pressure.

The distribution of the semi-major axis for 8 \( \mu m \) particles is bimodal (Fig. 1). This is because the rate of change for the semi-major axis is slowest near the turning points of the libration (Fig. 2a). As a result, these semi-major axis values contribute more to the distribution. The precise libration amplitudes are different for different particles of the same size, which is the reason why the peaks for 8 \( \mu m \) particles in Fig. 1 are wide. Particles of different grain size (\( >4 \mu m \)) also possess this bimodal property. However, the bimodality is buried for the whole Trojan dust population because different peaks of various grain sizes are superimposed onto each other.

There exist particles that are not trapped in the Jupiter 1:1 resonance, or which can escape from this resonance. Due to various perturbation forces, these particles are transported either outwards or inwards, which does not occur for the Trojan asteroids themselves. Some grains can be trapped in the Saturn 1:1 resonance. Following the same procedure as for Eqs. (1)–(4), we can calculate the conventional semi-major axis at the Saturn 1:1 resonance. A 2 \( \mu m \) particle trapped in the Saturn 1:1 resonance is taken as an example (Fig. 3), for which the resonant semi-major axis is \( a_{\text{Saturn}, 1:1} \approx 8.78 \) au. The particle is transported outwards and gets trapped in and escapes the Saturn 1:1 resonance several times.

There are also particles that can be trapped in higher order resonances with Jupiter. As an example we show the trapping in the Jupiter interior (3:4) resonance (Fig. 4) and (exterior) 4:3 resonance (Fig. 5) for 2 \( \mu m \) particles. The resonant arguments are \( \Psi_{3:4} = 3\lambda_{\text{eff}} - 4\lambda_{\text{Jupiter}} + \pi_{\text{eff}} \) and \( \Psi_{4:3} = 4\lambda_{\text{eff}} - 3\lambda_{\text{Jupiter}} - \pi_{\text{eff}} \). The resonant semi-major axes are calculated as \( a_{3:4} \approx 3.94 \) au and \( a_{4:3} \approx 5.78 \) au. In both cases, particles are trapped for more than 5000 yr. However, the trapping probabilities in the Saturn 1:1 resonance and the Jupiter higher order resonances are low.
4. Distributions of eccentricity $e$, longitude of pericenter $\sigma$, and inclination $i$

The eccentricity distributions for the L₄ asteroids and Trojan dust of all sizes peak close to $e_{\text{jupiter}} (\approx 0.049)$, as shown in Fig. 6. This is because in the elliptic restricted three-body problem, the values $\sigma = a_{\text{Jupiter}}$, $e = e_{\text{Jupiter}}$, and $\sigma = \sigma_{\text{Jupiter}} \pm 60^\circ$ are the stable equilateral solutions (e.g., Sándor & Érdi 2003; Robutel & Souchay 2010).

The peak value of the dust eccentricity distribution is slightly smaller than $e_{\text{Jupiter}}$. This is mainly because of the effects of P-R drag and solar wind drag. For large particles, the orbits are nearly Keplerian. Using the orbital average method, the effects of P-R drag and solar wind drag on eccentricity can be expressed as (Burns et al. 1979)

$$\left. \frac{\langle de \rangle}{dt} \right|_{\text{drag}} = -(1 + sw) \left( \frac{3Q_5Q_\rho}{4pr_g^2c^2} \right) \left( \frac{5e}{2a^2 \sqrt{1 - e^2}} \right),$$

where $sw$ is the ratio of solar wind drag to P-R drag, $Q_5$ is the radiation energy flux at one au, $Q_\rho$ is the solar radiation pressure efficiency, $r_g$ is the grain radius, and $c$ is the light speed. On average these two drag forces reduce the value of eccentricity for larger particles. Large eccentricities are induced for particles with grain sizes $\leq 2 \mu m$ (Fig. 6). These small particles are affected by the strong solar radiation pressure and Lorentz force, which increase the probability of encounters with Jupiter, Saturn, or other planets. All these effects can excite large eccentricities.

We do not see obvious patterns in the distributions of $\omega$ (argument of pericenter) and $\Omega$ (longitude of ascending node). Instead, we take a look at the distribution of $\sigma = \omega + \Omega$. For the L₄ asteroids and their dust, the distributions of $\sigma$ are shown in Fig. 7. The peak of the Trojans’ $\sigma$ distribution is about 60° larger than $\sigma_{\text{jupiter}}$. This is because $\sigma = \sigma_{\text{jupiter}} + 60^\circ$ is the stable equilateral solution in the elliptic restricted three-body problem (e.g., Sándor & Érdi 2003; Robutel & Souchay 2010), as mentioned above. To the knowledge of the authors, this peak with distribution of $\sigma$ for the Jupiter Trojan asteroids has not been shown in the literature to date.

Roughly, the distributions of $\sigma$ for the L₄ asteroids and dust have the same shape. However, we note that for Trojan dust $\Delta \sigma = \sigma_{\text{peak}} - \sigma_{\text{jupiter}} < 60^\circ$. The value of $\Delta \sigma$ becomes smaller with smaller grain size, if the grains can be trapped in the Jupiter 1:1 resonance. Seen from Fig. 7, for dust of all sizes, $\Delta \sigma \approx 45^\circ$; while for 4 $\mu m$ particles, $\Delta \sigma \approx 37^\circ$.

Compared to the distributions of $a$, $e$, and $\sigma$, the inclination distribution of dust is closer to that of the L₄ Trojans (Fig. 8). The reason is explained as follows. The variation of the inclination can be expressed as (Murray & Dermott 1999)

$$\frac{di}{dt} = \frac{r \cos(\omega + f)}{na^2 \sqrt{1 - e^2}} N,$$

where $r$ is the Jovian distance, $f$ is the true anomaly, $n$ is the mean motion, and $N$ is the normal component of the perturbation force relative to the orbital plane. Solar radiation pressure, P-R drag, and solar wind drag have no such normal component.
out. This explains the remaining inclination difference between the effect of the Lorentz force on inclination does not averageimplies that the dust orbit becomes non-Keplerian. As a result, βtively strong; moreover, the value ofL of the formation of the whole dust population is roughly consistent with that1979). Although the Lorentz force has a normal component with respect to the dust orbital plane, for large particles the Lorentz force is weak because of its dependence on the inverse square of the solar magnetic field rapidly changes with the 22 year period of the solar1 For small particles, the magnitude of Lorentz force is relatively strong; moreover, the value of1µ1m particles. Thus, these forces do not change orbital inclination (Burns et al.1979). Although the Lorentz force has a normal component with respect to the dust orbital plane, for large particles the Lorentz force is weak because of its dependence on the inverse square of the grain size. Besides, the polarity of the interplanetary magnetic field rapidly changes with the 22 year period of the solar cycle (Gustafson 1994; Landgraf 2000), so the average effect of the Lorentz force on inclination is very small (Fahr et al. 1995; Moro-Martín & Malhotra 2003). Also because larger particles can stay in the system for a longer time, the inclination distribution of the whole dust population is roughly consistent with that of the L4 Trojans for the most part.

For small particles, the magnitude of Lorentz force is relatively strong; moreover, the value of β is relatively large, which implies that the dust orbit becomes non-Keplerian. As a result, the effect of the Lorentz force on inclination does not average out. This explains the remaining inclination difference between L4 Trojans and Trojan dust (small wiggles in Fig. 8). Taking 1µm particles for instance, they can attain high inclination (black line in Fig. 8) due to the stronger Lorentz force (Fig. 9).

5. Distribution of the Tisserand parameter \( T_p \)

The Tisserand parameter is a nearly conserved quantity in the circular restricted three-body problem, derived as an approximation to the Jacobi constant (Tisserand 1889; Murray & Dermott 1999). In celestial mechanics, the Tisserand parameter is often used for orbit classification (Levison 1996; Levison & Duncan 1997). The Tisserand parameter with respect to Jupiter is defined as

\[
T_p = \frac{\alpha_{Jupiter}}{a} + 2 \cos i \sqrt{a \over \alpha_{Jupiter}} (1 - e^2) .
\]

(7)

Similar to the dynamical behavior of comets (Levison 1996; Levison & Duncan 1997), typical values of the Tisserand parameter for Jupiter Trojan asteroids satisfy \( 2 < T_p < 3 \). From our simulations, we know that dust particles keep for most of their dynamical evolution a value of \( T_p \) that is close to \( T_p \) of their sources. As a consequence, the L4 Trojans and dust particles ejected from them have similar distributions of \( T_p \) (Fig. 10). For the overwhelming part we have \( 2 < T_p < 3 \). For dust particles there is a very small portion with values of \( T_p > 3 \). This mainly attributes to particles in the size range \([1, 2] \) µm. For these grain sizes, the lifetime is long enough for strong solar radiation pressure to increase the \( T_p \) values. As an example the \( T_p \) distribution for 2µm particles is also shown in Fig. 10.

For dust released from the main belt asteroids (Dermott et al. 2002), we expect \( T_p > 3 \) as their sources. Thus, determination of the orbital elements from the measured dust velocity should allow us to distinguish particles that were released from Trojan asteroids and from main belt asteroids. We note that Jupiter-family comets also have typical values of Tisserand parameters in the range \( 2 < T_p < 3 \) (Levison 1996; Levison & Duncan 1997). However, for most of these comets the semi-major axes are much larger, or smaller, than those of Jupiter Trojans (5.2 au). Besides, eccentricities of Jupiter-family comets (>0.2) are larger than the typical eccentricities of Jupiter Trojans. Thus, it will be possible as well to distinguish dust released from Trojan asteroids and dust from Jupiter-family comets in terms of their semi-major axes and eccentricities.

6. Conclusions

In previous work, we developed a numerical model for dust particles ejected from the Jupiter Trojans, and derived their configuration in space (Liu & Schmidt 2018). In this work, we compare the orbital properties of these Trojan dust particles and the Jupiter L4 asteroids. We find that the peak of semi-major axis distribution for Trojan dust is smaller than that for Trojans, which is mainly due to solar radiation pressure. The distribution of the semi-major axis for grain sizes \( >4 \) µm is bimodal. A fraction of the particles can be trapped in the Saturn 1:1 resonance and Jupiter higher order resonances. The peak of the eccentricity distribution for Trojan dust is also smaller than that for Trojans,
which is because of the action of P–R drag. For the Trojan asteroids, the peak in the longitude of pericenter distribution is about 60° larger than Jupiter’s longitude of pericenter. For Trojan dust this difference is less than 60°, and it decreases with decreasing grain size. The inclination distributions of Trojans and Trojan dust are quite similar, except that small particles can attain large inclination due to the effect of the Lorentz force. The Trojan asteroids and most Trojan dust have typical values of Tisserand parameters in the range of two to three.
