Recent experiments show that shear-banded flows of semi-dilute worm-like micelles in Taylor-Couette geometry exhibit a flow instability in the form of Taylor-like vortices. Here we perform the non-axisymmetric linear stability analysis of the diffusive Johnson-Segalman model of shear banding and show that the nature of this instability depends on the applied shear rate. For the experimentally relevant parameters, we find that at the beginning of the stress plateau the instability is driven by the interface between the bands, while most of the stress plateau is occupied by the bulk instability of the high-shear-rate band. Our work significantly alters the recently proposed stability diagram of shear-banded flows based on axisymmetric analysis.

PACS numbers: 83.80.Qr, 47.50.-d, 47.50.Gj

Flows of complex fluids often differ dramatically from their Newtonian counterparts [1]. One of the most striking examples of such differences is the phenomenon of shear-banding which is widespread in flows of micellar solutions [1, 2], granular media [3], foams [4] and colloidal glasses [5]. Its name is derived from the observation that when sheared these materials often split into two or more bands of different shear rates, viscosities and viscoelastic properties [1, 2]. In semi-dilute solutions of worm-like micelles, shear-banding is often associated with the so-called shear-stress plateau – the range of applied shear rates $\dot{\gamma}_{app}$ for which the shear stress $\Sigma$ is approximately independent of $\dot{\gamma}_{app}$ [2, 6, 7]. Outside the stress plateau, simple 1D shear flow remains homogeneous, while for the values of $\dot{\gamma}_{app}$ on the plateau, it splits into two regions of simple shear flow with different shear rates [2].

Recent experiments with semi-dilute worm-like micellar solutions have demonstrated that this picture of steady 1D shear-banded flows only holds on average [8–11]. Visualisation experiments in flows between two rotating coaxial cylinders, the Taylor-Couette flow, have shown that on the stress plateau, there exist large instantaneous fluctuations in local stresses and the local position of the interface between the two bands that are associated with a 3D hydrodynamic instability [8–11]. This instability has the form of doughnut-shaped vortices threaded by the inner cylinder and stacked in the vorticity direction (Taylor-like vortices) and is mainly localised in the high-shear-rate band [11]. Its origin is not inertial due to the low flow velocities and large viscosities involved [2].

Presently, the precise nature of the instability driving the Taylor-like vortices and undulations of the interface remains unclear. Possible mechanisms include an instability driven by the presence of the interface (interfacial mode) or a bulk instability inside one or both bands (bulk mode). The interfacial mode is a viscoelastic analogue of the Kelvin-Helmholtz instability and arises in co-flows of several liquids with a discontinuity in their normal-stress differences across the interface [12]. The bulk mode, which has been observed in Taylor-Couette flow of polymer solutions, is driven by large values of the first normal stress difference $N_1$ in the bulk, and the presence of curved streamlines [13, 14]. Unlike Newtonian Taylor-Couette flow where the first instability results in an axisymmetric stack of Taylor vortices, linear stability analysis predicts that viscoelastic Taylor-Couette flow is unstable towards non-axisymmetric (wavy in the azimuthal direction) Taylor-like vortices [16].

Previous attempts to uncover the nature of the instability in the shear-banded Taylor-Couette flow focused on the axisymmetric version of this flow [15]. By performing numerical simulations, Fielding has concluded that micellar solutions split into three groups depending on their material properties: fluids with low values of the first normal stress difference $N_1$ in their high-shear-rate band exhibit the interfacial instability [16], while fluids with high values of $N_1$ exhibit the bulk instability in curved geometries [15]. For intermediate values of $N_1$, the flow was predicted to be stable, and the precise position of this region was found to depend on the curvature of the Taylor-Couette cell [15]. The main problem with this scenario is that the fluid used by Lerouge et al. [8, 10, 11] to observe the instability most probably belongs to the stable region of the stability diagram proposed in [15] (see Supplemental Material), casting doubt on the proposed mechanism.

In this Letter we show that this contradiction is resolved if one relaxes the assumption of axisymmetric flow. We perform a linear stability analysis of the shear-banded Taylor-Couette flow with respect to non-axisymmetric disturbances for a model fluid with material properties similar to the solutions used in the experiments by Lerouge et al. [8, 10, 11]. We find that while axisymmetric perturbations are stable as predicted by Fielding [15], non-axisymmetric modes are unstable for all applied...
shear rates on the stress plateau. The nature of the instability depends on the applied shear rate: very close to the beginning of the plateau, we find this is dominated by the interfacial mode, while most of the plateau is unstable via the bulk mode in agreement with the observations by Fardin et al. [11].

Our model consists of the momentum conservation equation in the limit of negligible inertia,

$$-\nabla p + \eta_s \Delta \tau + \nabla \cdot \tau = 0,$$

and the diffusive Johnson-Segalman (DJS) equation [12] [13] [14] for the viscoelastic stress $\tau$:

$$\tau + \lambda \left( \frac{1 + a}{2} \frac{\tau}{\nabla \cdot \tau} + \frac{1 - a}{2} \nabla^2 \tau \right) - \lambda^2 \nabla^2 \tau = \eta_p \left( \nabla v + \nabla v^\top \right),$$

(2)

where $\eta$ and $\eta_p$ are the viscosities of the Newtonian “solvent” and viscoelastic (micellar) components, and $\lambda$ is the Maxwell relaxation time. The slip parameter $a$ controls the degree of non-affine deformations under flow [17] and Eq. (2) predicts a non-monotonic flow curve (shear-banding) as long as $a \neq \pm 1$ and $\eta_p/\eta_s > 8$. The stress-diffusion term $\lambda^2 \nabla^2 \tau$ in Eq. (2) prevents stress variations on scales smaller than $\lambda$ and uniquely selects the value of the plateau shear stress [18]. The lengthscale $l$ sets the size of structural correlations in the fluid, and controls the width of the interface between the bands and the extent of the near-wall layers where the bulk behaviour changes rapidly in order to match the boundary conditions. Finally, we assume that the fluid is incompressible, $\nabla \cdot v = 0$, and apply the no-slip boundary conditions for the velocity $v$ and the no-flux boundary conditions for the stress tensor $\tau$ [15] [16].

We consider the Taylor-Couette flow between two coaxial cylinders. The inner cylinder of radius $R_1$ rotates with the angular velocity $\Omega$, while the outer cylinder of radius $R_2$ is kept stationary. The fluid flows in the gap of size $d = R_2 - R_1$ and the relative velocity of the Taylor-Couette cell is set by $\epsilon = d/R_1$. We choose the parameters in our model, Eqs. (1,2), to closely match their experimental values as used by Lerouge et al. [8] [10] [11] and set $R_1 = 13.33 \text{ mm}$ and $d = 1.13 \text{ mm}$. To find the relaxation time $\lambda$, the slip parameters $a$ and the viscosities $\eta_s$ and $\eta_p$, we fit the rheological predictions of the Johnson-Segalman model in plane homogeneous shear flow to the cone-and-plate measurements for a solution used in [10].

In Fig. 1 we compare the experimental data (crosses, courtesy of S. Lerouge) against the fit to the Johnson-Segalman model (solid and dashed lines) with $\lambda = 0.51 \text{ s}$, $a = 0.985$, $\eta_s = 1.1 \text{ Pa} \cdot \text{s}$ and $\eta_p = 33.0 \text{ Pa} \cdot \text{s}$. These parameters are similar to the linear rheological measurements of [10], $\lambda \approx 0.23 \text{ s}$ and $\eta_s/\eta_p \approx 55 \text{ Pa} \cdot \text{s}$. We mostly consider two values of the structural lengthscale, $l = 13 \mu\text{m}$ and $l = 4 \mu\text{m}$, which are consistent with the experimentally determined values [10] [19] [20].

First we introduce cylindrical coordinates $(r, \theta, z)$ and solve the equations of motion [12] numerically for the steady 1D shear-banded profile using a pseudospectral Chebyshev-tau method [21]. To accurately resolve sharp interfaces we split the computational domain into three regions, two for each shear band and one corresponding to the interface, and use adaptive domain decomposition algorithm to discretize them independently. A similar method was employed in [22].

The linear stability analysis is performed by perturbing the 1D profile with 3D perturbations of the form $(\psi, \tau, p) \sim \exp(\alpha t + ikz + im\theta)$, linearising the equations of motion, and solving the resulting generalised eigenvalue problem. Below, the applied shear rate is reported in terms of the dimensionless Weissenberg number $Wi = \lambda \Omega / (\epsilon (\epsilon + 2))$. 

FIG. 1. Total shear stress $\Sigma$ and first normal-stress difference $N_1$ as a function of the applied shear rate $\dot{\gamma}_{app}$. Crosses - experimental measurements by S. Lerouge et al. [10] in a cone-and-plate geometry; solid line - JS constitutive curve for planar homogeneous shear flow; dashed line - prediction of the JS model in planar shear-banded flow.

FIG. 2. (left) Maximum growth rate $\Re(\sigma^*)$ as a function of $Wi$ on the stress plateau (boundaries denoted by the dashed lines) for various values of the diffusion length $l$: squares – $l = 73 \mu\text{m}$, circles – $l = 13 \mu\text{m}$, triangles – $l = 4 \mu\text{m}$. (right) Axial and azimuthal wavelengths $k^\star$ and $m^\star$ of the most unstable mode as a function of $Wi$ for $l = 13 \mu\text{m}$. The lines are drawn to guide the eye.
**FIG. 3.** (top) Superimposed spectra showing the most unstable eigenvalue for the shear-banded (dots – \( l = 13 \mu m \)) and the auxiliary (crosses – \( l = 4 \mu m \)) setup. (a) \( Wi = 29, k = 20.54 \) and \( m = 21 \); (b) \( Wi = 3.0, k = 14.4 \) and \( m = 30 \). (bottom) Contour plots of the dispersion relation \( Re \sigma(k, m) \) as a function of \( m \) and \( k \). White triangle marks the most unstable eigenmode. (c) \( Wi = 29 \) and \( l = 4 \mu m \), green dashed lines – contour plot for the auxiliary system; (d) \( Wi = 3.0 \) and \( l = 4 \mu m \) showing two types of instability.

In Fig. 2 we plot the real part of the most unstable eigenvalue \( \sigma^* \) and the corresponding wavelengths \( k^* \) and \( m^* \) as a function of \( Wi \). We find that the shear-banded profile is unstable on the whole plateau, contrary to the axisymmetric prediction for our parameters [15].

In order to determine whether the instability is interfacial or bulk, we employ the following method. For every \( Wi \) along the stress plateau, we construct an auxiliary Taylor-Couette system that models only the high-shear-rate band of the original flow. The flow in the auxiliary system is homogeneous (not shear-banded) and has the same laminar velocity and stress profiles as the original high-shear-rate band. This is achieved by choosing the gap size of the auxiliary flow cell to be equal to the width of the high-shear-rate band and rotating both inner and outer cylinders, while keeping \( R_1 \) and the DJS parameters the same as above. As the result, the high-shear-rate band and its model version only differ in the nature of their outer boundary – the interface with the low-shear-rate band (soft) or a wall (hard), respectively. (For a recent discussion of the soft vs hard boundary conditions in the context of shear-banding, see [23].) We then compare the eigenspectra in both setups: the eigenmodes that appear in both systems clearly correspond to the bulk instability. No instability was found when the same procedure was applied to the low-shear-rate band.

In Fig. 3(a) we show the comparison of the shear-banded and (homogeneous) auxiliary systems at \( Wi = 29 \) (near the upper end of the stress plateau) for \( k^* \) and \( m^* \), the most unstable values of \( k \) and \( m \). In Fig. 3(c) we present the contour plot of the real part of the leading eigenvalue for different values of \( k \) and \( m \) in both setups. In spite of the different boundary conditions in the two systems, we observe that their leading eigenvalues coincide, which we attribute to the small size of the low-shear-rate band at high \( Wi \) and the influence of the no-slip boundary condition at the wall on the high-shear-rate band. This coincidence implies that the instability originates in the bulk of the high-shear-rate band. Moreover, we find no local maxima besides the eigenvalue family corresponding to the most unstable bulk mode, which is dominant in a wide range of \( Wi \sim 10 - 30 \). The fact that we see a 3D instability where the axisymmetric analysis predicted stable flow [15], is perhaps not surprising since the first instability predicted for purely elastic Taylor-Couette flow of polymer solutions, which is similar to our bulk instability, is non-axisymmetric [24].

For small values of the applied shear rate the situation is different. As can be seen from Fig. 3(b) for \( Wi = 3.0 \), the most unstable mode of the shear-banded profile does not coincide with any eigenvalue of the auxiliary system, and we conclude that this instability is driven by the
interface. We also observe, Fig.3(d), that the shape of
this eigenvalue family on the \( \Re \sigma(k,m) \) contour plot is
different from the bulk mode of Fig.3(c) and is similar
to what was found by Fielding for the interfacial mode
in plane shear [16].

At intermediate values of the applied shear rate, both
the interfacial and bulk modes are unstable, as can be seen from Fig.3(e). The velocity profiles corresponding to
the two peaks in the \( \Re \sigma(k,m) \) contour plot differ funda-
mentally: one has its maximum velocity in the vicinity of
the interface, while the other is mostly present in the bulk
(see Supplemental Material). The height of the bulk peak
rapidly overtakes that of the interfacial peak as \( \dot{\gamma} \) is in-
creased. The transition from the interfacial to the bulk
mode takes place at the critical value of the Weissenberg
number that depends on the diffusive length: \( Wi_{crit} \approx 10
\) for \( l = 13 \mu m \), and \( Wi_{crit} \approx 6 - 8 \) for \( l = 4 \mu m \).

Our use of the auxiliary Taylor-Couette systems to
determine the nature of the instability is motivated by
the observation that decreasing the value of the diffusion
length \( l \) enhances both modes of instability. Indeed, this
parameter not only controls the width of the interface,
thus affecting the interfacial mode [10], but also sets the
minimal spatial extent of stress gradients in the fluid,
and hence has a strong effect on the bulk mode as well.
Therefore, one cannot deduce the nature of an eigenmode
by observing how its eigenvalue changes with \( l \).

In summary, we presented theoretical evidence that
the shear-banded Taylor-Couette flow is unstable with
respect to non-axisymmetric perturbations. For param-
eters matched to the experiments by Lerouge et al.
[8] [10] [11], we find the interfacial instability only at the
beginning of the stress plateau, while most of the plateau
is occupied by the bulk instability. These results are con-
sistent with the observations by Fardin et al. [11], where
the Taylor vortices, localised mostly in the high-shear-
rate band, were observed in a wide range of shear rates
on the stress plateau. Moreover, we find instabilities
with the axial wavelengths of order of a few millimeters,
roughly in agreement with the asymptotic (non-linear)
wavelengths observed by Lerouge et al. [10]. Potentially,
our prediction is further supported by recent experiments
of Decruppe et al. [25], who observed azimuthal undula-
tions of the interface. However, unlike [8] [10] [11], no axial
interface perturbations were found in their experiment,
and its relevance to our work remains an open question.

As was noted by Fielding [15], the Taylor-Couette flow
of worm-like micellar solutions is unique as it brings to-
gether three types of instabilities: shear banding itself
and the interfacial and bulk ones. The stability diagram
proposed in [15], based on the axisymmetric analysis, in-
cluded regions of interfacial and bulk instabilities sep-
parated by a window of stable shear-banded flow, and
any given micellar solution was predicted to belong to
only one of these regions. Our results, based on the non-
axisymmetric linear stability analysis, suggest that both
types of instabilities can be found for a given micellar
solution. We speculate that the whole curvature-\( N_1 \)
instabiliy diagram may be occupied by the unstable region,
with the position of the transition between the interfacial
and bulk modes, \( Wi_{crit} \), being determined by the normal
stresses in the high-shear-rate band: for larger values of
\( N_1 \) the transition would happen at smaller \( Wi_{crit} \).

We would like to thank Sandra Lerouge for providing the rheological data used in Fig.1 and Mike Cates, Marc
Fardin and Sandra Lerouge for useful discussions. AM

ation Fellowship (grant EP/I004262/1).

SUPPLEMENTAL MATERIAL

Position of the solution used by Lerouge et al. [10]
on the stability diagram of Fielding [15]

Since the relative curvature of the flow cell used by
Lerouge et al. [10] was fixed at 1.13/13.33 \( \approx 0.08 \), the stability of the shear-banded flow as predicted by Fielding
[15] only depends on the model parameter \( 1/(1-a) \). For this value of the curvature, the fluid was found to ex-
hibit the interfacial instability for \( 1/(1-a) < 10 \), the bulk
instability for \( 1/(1-a) > 600 \), or to be stable for interme-
diate values of \( 1/(1-a) [15] \). The position of the boundaries
between different types of instability are dependent on
the parameter \( \eta_s/\eta_p \), and the values quoted above are
for \( \eta_s/\eta_p = 0.05 [15] \).

In plane homogeneous (not banded) shear flow, the JS model predicts the following expression for the first
normal stress difference \( N_1 \) as a function of the applied shear rate \( \dot{\gamma}_{app} \):

\[
N_1 = \frac{2\lambda \eta_p \dot{\gamma}_{app}^2}{1 + \lambda^2 \dot{\gamma}_{app}^2 (1 - a^2)}.
\]

Eq. (3) predicts that \( N_1 \) approaches a horizontal asymp-
tote as \( \dot{\gamma}_{app} \) tends to infinity, and the normal-stress differ-
ence of the high-shear-rate band \( N_1^b \) is well approximated
by the asymptotic value of \( N_1 \). In the limit \( a \to 1 \), Eq.(3)
yields:

\[
N_1^b \approx \frac{\eta_p}{\lambda (1 - a)},
\]

and hence, the model parameter \( 1/(1-a) \) is proportional to
the value of the first normal stress difference in the high-
shear-rate band. Using the data of S. Lerouge, Fig.1 of
the main text, we estimate \( N_1^b \approx 3 \times 10^3 Pa \). The
relaxation time in the linear regime was found to be \( \lambda \approx
0.23s [10] \), as mentioned in the main text. From the slope
of the \( \Sigma (\dot{\gamma}_{app}) \) at small applied shear rates, the total shear
viscosity is in the range of \( 20-50 Pa \cdot s \) which is consistent
with the linear rheology value \( 55 Pa \cdot s \) found in [10]. Since
\( \eta_s \ll \eta_p \), we approximate \( \eta_p \) by the value of the total zero-shear viscosity. This yields the following estimate:

\[
14 < \frac{1}{1-a} < 58.
\]

As mentioned above, the exact value of the boundary between stable and unstable regions of the stability diagram proposed by Fielding [15] depends on \( \eta_s/\eta_p \) which is difficult to infer experimentally. Therefore it is possible that the lowest end of the range (5) belongs to the region of the interfacial instability, while most of the range is in the stable region of the stability diagram. Nevertheless, both are incompatible with the observation by Fardin et al. [11] of a bulk instability.

Moreover, the model parameter \( a = 0.985 \) used in this study [26] gives \( 1/(1-a) \approx 67 \) – well inside the stable region of the stability diagram of Fielding. We confirmed this by studying the linear stability with respect to the axisymmetric modes and found no instability. However, the flow does exhibit a non-axisymmetric instability, which is the main finding of our paper.

Schematic view of the original and auxiliary Taylor-Couette setups

In the auxiliary setup, the interface between the bands is replaced by a solid boundary that moves with the same velocity as the low-shear-rate band in the original setup, see Fig[4]. The only difference between the two setups is the nature of the outer boundary condition. In the original case, the velocities at the outer boundary of the high-shear-rate band have to match the corresponding velocities in the low-shear-rate band (a soft boundary), while in the auxiliary setup, the presence of the rotating outer wall imposes the no-slip boundary condition on the velocity.

At high Weissenberg numbers, the low-shear-rate band occupies only a small portion of the gap in the original setup, and the high-shear-rate band experiences the influence of the no-slip condition imposed at the outer wall; the interface, therefore, acts as a relatively hard boundary. In this case, the bulk eigenmodes in the spectra of the original and auxiliary systems coincide, as can be seen from Fig.3(a). When the Weissenberg number is decreased, corresponding to a wider low-shear-rate band, the boundary condition at the interface starts to be “softer” and the agreement between the eigenspectra of the original and auxiliary systems starts to deteriorate.

Velocity profiles associated with the interfacial and bulk modes at \( Wi = 6.4 \) (see Fig.3(e))

![Image of velocity profiles](image-url)

FIG. 5. Velocity profiles in the \( r - z \) plane for \( Wi = 6.4 \) and \( l = 4 \mu m \): (top) first peak of the dispersion relation at \( k = 14.4 \) and \( m = 6 \), the interfacial mode; (bottom) second peak at \( k = 25 \) and \( m = 24 \), the bulk mode. The red lines indicate the position and the width of the computational domain comprising the interface between the bands.

[26] Note that the range (3) is based on the value of the relaxation time measured from linear rheology, which is somewhat different from the value that we found by fitting the overall shape of the Σ and Ν1 curves. That is why our value of $1/(1-a)$ lies slightly outside the range (5).
