Abstract
During metamorphosis, the olfactory system of anuran tadpoles undergoes substantial restructuring. The main olfactory epithelium in the principal nasal cavity of Xenopus laevis tadpoles is associated with aquatic olfaction and transformed into the adult air-nose, while a new adult water-nose emerges in the middle cavity. Impacts of this metamorphic remodeling on odor processing, behavior, and network structure are still unexplored. Here, we used neuronal tracings, calcium imaging, and behavioral experiments to examine the functional connectivity between the epithelium and the main olfactory bulb during metamorphosis. In tadpoles, olfactory receptor neurons in the principal cavity project axons to glomeruli in the ventral main olfactory bulb. These projections are gradually replaced by receptor neuron axons from the newly forming middle cavity epithelium. Despite this reorganization in the ventral bulb, two spatially segregated odor processing streams remain undisrupted and behavioral responses to waterborne odorants are unchanged. Contemporaneously, new receptor neurons in the remodeling principal cavity innervate the emerging dorsal part of the bulb, which displays distinct wiring features. Glomeruli around its midline are innervated from the left and right nasal epithelia. Additionally, postsynaptic projection neurons in the dorsal bulb predominantly connect to multiple glomeruli, while half of projection neurons in the ventral bulb are uni-glomerular. Our results show that the “water system” remains functional despite metamorphic reconstruction. The network differences between the dorsal and ventral olfactory bulb imply a higher degree of odor integration in the dorsal main olfactory bulb. This is possibly connected with the processing of different odorants, airborne vs. waterborne.

Introduction
Tadpoles of most anuran amphibians share a similarly structured olfactory periphery, consisting of the main olfactory epithelium in the principal nasal cavity (PC), a vomeronasal organ (VNO), as well as some minor additional epithelial surfaces (Jungblut et al. 2021; Weiss et al. 2021). This is well documented for all major groups of anurans: Archaeobatrachians (Benzekri and Reiss 2012), Mesobatrachians (Manzini and Schild 2010) and Neobatrachians (Jermakowicz et al. 2004; Jungblut et al. 2011, 2017; Nowack and Vences 2016; Quinzio and Reiss 2018).

The transition from an aquatic tadpole to a more or less water-independent adult frog requires the neuronal network associated with odor processing to restructure and rapidly adapt to the new habitat (Duellman and Trueb 1994; Wells 2007; Reiss and Eisthen 2008). During metamorphosis, the olfactory periphery transforms into a tripartite chamber system, consisting of the main olfactory epithelium in the PC, a middle cavity (MC) lined with non-sensory epithelium in most species, and the VNO (Helling 1938; Reiss and Eisthen 2008). While the larval system (PC and VNO) is specialized for the detection of waterborne odors, the sensory epithelium in the adult PC is associated with sensing volatile odors. In some anuran species, a small patch of sensory epithelium on the floor of the PC — the recessus olfactorius — is also tuned to detect waterborne odors (for reviews, see Reiss and Eisthen, 2008; Weiss et al., 2021).
In contrast to many other anurans, the pipid frog *Xenopus laevis* is secondarily aquatic. Adult *Xenopus* are fully water-dwelling (Wells 2007; Reiss and Eisthen 2008) and only occasionally move overland (Du Plessis 1966; Measey 2016). The special ecology of adult *Xenopus* is reflected in the presence of a specialized “water-nose” in the MC, which starts to form around premetamorphic stage 51 after Nieuwkoop and Faber (Föske 1934; Nieuwkoop and Faber 1994; Reiss and Burd 1997a, b; Hansen et al. 1998; Higgs and Burd 2001; Dittrich et al. 2016). The epithelium in the adult MC exhibits strong similarities with the larval PC. It contains both major types of olfactory receptor neurons (ORNs, ciliated and microvillous; Hansen et al. 1998), is responsive to common waterborne olfactory stimulants like amino acids (Sorensen and Caprio 1998; Syed et al. 2017), and expresses a similar set of olfactory receptors (Freitag et al. 1995, 1998; Amano and Gascuel 2012; Syed et al. 2013, 2017).

During metamorphosis, major remodeling occurs in the PC of larval *Xenopus* caused by massive cell death and replacement of ORNs (Hansen et al. 1998; Higgs and Burd 2001; Dittrich et al. 2016). The remodeled adult PC is eventually composed of only ciliated ORNs and expresses olfactory receptors putatively responsive to airborne odorants (Freitag et al. 1995; Mezler et al. 1999, 2001), thus assuming the role of the adult “air nose” (Föske 1934; Hansen et al. 1998; Syed et al. 2017). In contrast, the VNO does not seem to change significantly during metamorphosis in regard to its cellular composition or function (Hansen et al. 1998; Dittrich et al. 2016).

The functional and cellular segregation of the olfactory periphery also translates to the level of the olfactory bulb. Receptor neurons in the VNO project their axons towards their target structures, the glomeruli, in the accessory olfactory bulb (Reiss and Eisthen 2008; Jungblut et al. 2012). ORNs residing in the PC of larval *Xenopus* project their axons to glomeruli arranged in the ventral portion of the main olfactory bulb (vMOB) (Reiss and Burd 1997b; Weiss et al. 2020a). During metamorphosis, these axonal projections from the PC to the vMOB are replaced by ORN axons originating in the newly formed MC, the adult “water nose” (Key and Giorgi 1986; Hofmann and Meyer 1991; Franceschini et al. 1992; Reiss and Burd 1997b). Newly generated ORNs in the PC are projecting their axons towards the dorsal part of the main olfactory bulb (dMOB) during metamorphosis (Hofmann and Meyer 1991; Reiss and Burd 1997b; Gaudin and Gascuel 2005). Since it is solely innervated by ORNs residing in the adult “air-nose,” the dMOB is putatively associated with the processing of volatile odorants (Föske 1934; Reiss and Eisthen 2008; Weiss et al. 2021).

Functionally, the ORN axonal projections to the vMOB of *Xenopus* tadpoles have been shown to be segregated into two major odor processing streams: projections to laterally located glomeruli use a second messenger cascade dependent on phospholipase C and diacylglycerol (DAG), while projections to medially located glomeruli are dependent on the adenylate cyclase and use cyclic adenosine monophosphate (cAMP) as a second messenger (Gliem et al. 2013; Sansone et al. 2014). A substantial portion of the lateral glomeruli are responsive to amino acids and putatively innervated by microvillous ORNs (Gliem et al. 2013). Medially located glomeruli are putatively connected to ciliated ORNs and mainly respond to alcohols, aldehydes, and amines instead (Gliem et al. 2013). While there is evidence that the anatomy of the glomeruli in the vMOB remains stable during metamorphosis (Gaudin and Gascuel 2005; Weiss et al. 2020a), it is still unknown whether the innervation shift from the larval PC to the adult MC affects its function and/or its behavioral output.

Odor information transferred to the glomeruli in both parts of the MOB is subsequently relayed to the postsynaptic cells, the projection neurons (Imamura et al. 2020). In amphibians, these neurons feature one or more apical dendrites that terminate in densely branched tufts within glomeruli, and an axon projecting to higher brain centers (Jiang and Holley 1992b; Dryer and Graziadei 1994; Nezlin et al. 2003; Imamura et al. 2020). It has been shown in other vertebrates that the morphology of projection neurons varies based on their function or their association with distinct olfactory subsystems (Nagayama et al. 2014; Imamura et al. 2020; Braubach and Croll 2021). In amphibians, such analyses are lacking so far.

In the present work, we analyze the neuronal network restructuring of the MOB during metamorphosis on an anatomical, functional, and behavioral level. We show that ORN axonal projections from the larval PC to the vMOB are progressively replaced by ORN axons originating in the newly formed MC. Despite these massive reorganization processes, the functional segregation into two separate odorant processing streams in the vMOB remains stable. Similarly, the remodeling does not change behavioral responses to amino acids, implying that connections to higher brain centers remain intact during the process. Axons from newly developing ORNs in the remodeled PC project to the dMOB, forming an unpaired structure around the interhemispheric midline. We show that the dMOB network follows a wiring logic distinct from the vMOB, with a progressively higher number of ORN axons projecting to glomeruli in the contralateral hemisphere. Additionally, the populations of postsynaptic projection neurons of the vMOB and the dMOB differ morphologically, revealing a higher prevalence of multi-tufted neurons connected to multiple glomeruli associated with the dMOB. These features point towards a higher degree of integration between the hemispheres and across several glomeruli in the dMOB, possibly adaptive to the processing of volatile odorants. The processing of waterborne
odorants in the postmetamorphic vMOB, on the other hand, seems to mirror the larval system.

**Material and methods**

**Animals and tissue preparation**

All animals used in this study were wild type or albino *Xenopus laevis* (both sexes), kept and bred at the University of Giessen at a water temperature of 20 °C in water tanks with constant water circulation. Developmental stages were defined according to Nieuwkoop and Faber (Nieuwkoop and Faber 1994). Before experimental procedures, the animals were anesthetized using 0.02% MS-222 (ethyl 3-aminobenzoate methanesulfonate; TCI Germany) in tap water. For tissue preparation, anesthetized animals were killed by severing the transition between the brainstem and spinal cord. For lower staged animals, a tissue block containing the noses and the rostral part of the telencephalon was removed. For higher staged animals, the olfactory nerve was cut close to the noses and the entire brain was taken out of the cartilage. All animal procedures were performed in accordance with the guidelines for Laboratory animal research of the Institutional Care and Use Committee of the University of Giessen (V 54 – 19 c 20 15 h 01 GI 15/7 Nr. G 2/2019; 649_M; V 54 – 19 c 20 15 h 02 GI 15/7 KTV 7/2018).

**Tracings of olfactory receptor neurons via fluorophore-coupled WGA and electroporation**

For bulk loadings of olfactory projections from the nose to the MOB, we filled the nasal cavities with droplets of approx. 3 µl of fluorophore-coupled wheat germ agglutinin (WGA Alexa Fluor 488 or 594 conjugate, Thermo Fisher) diluted at a concentration of 10 mg/ml in saline Frog Ringer’s (in mM: 98 NaCl, 2 KCl, 1 CaCl2, 2 MgCl2, 5 glucose, 5 Na-pyruvate, 10 Hepes, pH 7.8). For bulk electroporations, we placed dried dye crystals of fluorophore-coupled dextrans (Alexa Fluor dextran 488, 594, Cascade Blue dextran, Thermo Fisher or Cal520 dextran conjugate, AAT Bioquest, 10 kDa, 3 mM in Frog Ringer’s) in the nostrils and applied six electric square pulses using two platinum electrodes (15 V, 25 ms duration at 2 Hz with alternating polarity) to each nostril (for detailed protocol see Weiss et al. 2018). After the procedures, animals were left to recover for at least 24 h before tissue preparation and imaging.

**Sparse cell electroporation in the olfactory epithelium and the olfactory bulb**

We sparsely electroporated ORNs in the nasal epithelia of the PC/MC and projection neurons in the vMOB/dMOB using micropipettes pulled from borosilicate glass capillaries (Warner instruments, resistance 10–15 MΩ) filled with fluorophore-coupled dextrans (Alexa Fluor dextran 488 and 594; 3 mM in Frog Ringer’s). The dye-filled micropipettes were mounted on the headstage of a single cell electroporator (Axoporator 800A; Axon Instruments, Molecular Devices) equipped with a wire electrode and approached cells in the olfactory epithelium (PC/MC) or the MOB using a micro-manipulator. A 500-ms train of square voltage pulses (50 V, single pulse duration 300 µs at 200–300 Hz) was applied.

For ORN labeling, the animals were first anesthetized and sparse cell electroporation was repeated at multiple locations using Alexa Fluor 488 dextran in the MC and Alexa Fluor 594 dextran in the PC to trace their respective projections during metamorphosis. After the procedure, animals were left to recover for at least 24 h prior to image acquisition (Hassenklöver and Manzini 2014). Sparse labeling of projection neurons in the MOB was conducted in an excised tissue block containing the olfactory system. We fixed the bulb and the caudal portion of the olfactory nerve under a platinum grid strung with nylon threads, approached the micropipette to the cell layer containing MOB projection neurons, and applied the voltage pulse trains as described above (detailed protocol in Weiss et al. 2018).

**Image acquisition and processing of morphological images**

Images were acquired as multi-color virtual image stacks with a z-resolution of 1–3 µm using multiphoton microscopy (Nikon A1R-MP) at an excitation wavelength of 780 nm. We used ImageJ (Schindelin et al. 2012; RRID:SCR_003070) to adjust the brightness and contrast of the image stacks and applied a median filter to remove pigmentation-derived artifacts in some images. Separate images were stitched together where necessary (Preibisch et al. 2009). For thresholding analyses conducted on the image-stacks, we eliminated tissue-derived autofluorescence by subtracting the blue-wavelength color channel (when no blue-emitting dye was introduced into the tissue). Images are presented as maximum intensity projections along the z-axis or in 3D using the 3D-viewer implemented in ImageJ.

**Functional calcium imaging and data processing**

For functional calcium imaging in the vMOB, we loaded the ORNs with a calcium sensitive dextran coupled dye (Cal 520 dextran conjugate, 10 kDa, AAT Bioquest; 3 mM in Frog Ringer’s) via bulk electroporation (Weiss et al. 2018) as described above. After killing the animal, we cut out the tissue block containing the noses and the anterior part of the brain and removed the ventral palatal tissue as well as tissue around the sensory epithelia to facilitate odorant flow into the nasal cavities. The tissue block was...
positioned on the stage of the multiphoton microscope using a platinum grid strung with nylon threads. A perfusion manifold with silicone tubing outlet (Milli Manifold; ALA Scientific) connected to a gravity-fed multi-channel perfusion system (ALA-VM-8 Series; ALA Scientific) was positioned in front of the nasal cavity and a constant Ringer’s flow was established. Ringer’s was constantly perfused, leading to a syringe needle connected to a peristaltic pump via silicone tubing. Fast volumetric recordings of the ORN axon terminals in the glomeruli of the vMOB were made using the resonant scanning mode of a multiphoton microscope (780 nm excitation wavelength). We measured time series of 3D virtual image stacks (lateral dimensions: 509×509 µm, 512×512 pixel; axial dimensions: 180–300 µm, inter-plane distance 4–7 µm) at 0.5–1 Hz per image stack (Offner et al. 2020). Stimuli were applied with a duration of 5 s and an inter-stimulus interval of 60 s and repeated at least twice. The stimuli used were as follows: amino acid mixture: L-valine, L-leucine, L-isoleucine, L-methionine, glycine, L-serine, L-threonine, L-cysteine, L-arginine, L-lysine, L-histidine, L-tryptophan, L-phenylalanine, L-alanine, L-proline (100 µM in Frog Ringer’s solution); amine mixture: 2-phenylethylamine, tyramine, butylamine, cyclohexylamine, hexylamine, 3-methylbutylamine, N,N-dimethylamylamine, 2-methylbutylamine, 1-formylpiperidine, 2-methylpiperidine, N-ethylecyclohexylamine, 1-ethylpiperidine, piperidine (100 µM in Frog Ringer’s solution); bile acid mixture: taurocholic acid, cholic acid, glycholic acid, deoxycholic acid (100 µM in Frog Ringer’s solution); odorant mixture: mixture of amino acids (excluding proline and alanine), amines, bile acids, alcohols and aldehydes (positive control, 50 µM in Frog Ringer solution) (Gliem et al. 2013); Frog Ringer’s solution (negative control); forskolin, a direct stimulant of the adenylate-cyclase and the cAMP second messenger pathway. Forskolin was dissolved in DMSO (stock of 10 mM) and used at a final concentration of 100 µM. All chemicals were purchased from Sigma-Aldrich. The mixtures were stored as frozen aliquots and diluted to their final concentration shortly before the experiments.

Data evaluation was done using Python. A piecewise-rigid motion correction algorithm was applied to remove motion artifacts (Pnevmatikakis and Giovannucci 2017). We used the CalImAn toolkit for calcium imaging data to generate denoised and deconvolved templates of the 3D image stacks (Pnevmatikakis et al. 2014, 2016; Friedrich et al. 2017; Giovannucci et al. 2019). These templates were used for maximum intensity projections along the z-axis of fluorescence intensity difference maps. Intensity difference maps resulted from the difference between the peak fluorescence intensity of post-stimulus responses (averaged from three timeframes) and baseline fluorescence prior to stimulus onset (averaged from five frames). Individual timeframes had a duration between 1.5 and 2 s. Responding regions were selected according to the following criteria: (i) regions had to be bigger than 100 pixels. (ii) They had to be reactive to at least one applied stimulus with a stimulus-evoked fluorescence intensity amplitude exceeding the average of all median values calculated for the amplitudes of each responding region in the dataset. (iii) The deconvolved timeseries generated by CalImAn had to pass an additional quality control, comparing them to the raw traces and discarding regions outside the boundaries of the glomerular clusters (using an interactive custom written Python script).

Changes in fluorescence of responsive regions over time were baseline corrected using asymmetric least squares smoothing (Eilers and Boelens 2005) and response tuning profiles were determined by normalizing each individual fluorescence intensity timeseries by its maximum intensity value (baseline: 0, maximum: 1). We then defined a threshold below which to ignore amplitude peaks in the expected peak response intervals (12.5%). The tuning profiles of responding regions were then defined by the set of stimuli that led to response amplitudes above 12.5% of the maximum amplitude of the respective time series.

For the spatial analysis of response profiles, responsive regions were first sorted according to their tuning profiles into forskolin-responsive (fsk +) and non-responsive (fsk −) regions. Both groups of regions were subcategorized based on their further response profiles to the applied odorant mixtures. A region’s position within the glomerular clusters was measured in relation to manually defined points at the medial–lateral and anterior–posterior edges of the ORN axonal projections in each individual vMOB. Along these two axes, we estimated the density of responsive regions using Gaussian kernel density estimates. Scott’s rule implemented in the Python library SciPy (https://scipy.org/) was used to calculate the estimator bandwidth (Scott 1992; Virtanen et al. 2020). Analysis of ORN projections to the MOB

The volumes of the ventral and dorsal portions of the ORN projections in the MOB (presented in Fig. 1) were manually annotated based on their visual outlines in the image stacks and measured using the Segmentation Editor implemented in ImageJ (Schindelin et al. 2012). They were subsequently analyzed using Python. The data show the percent share of ORN projections in the dMOB and the vMOB relative to the volume of the entire ORN projections (dMOB + vMOB). Projections in both hemispheres were summed up for this analysis.

For the analysis of MC and PC projections to the MOB (shown in Fig. 2), we separated image planes containing the vMOB and the dMOB and subsequently reduced the two
image stacks to maximum intensity projections along the z-axis. Images were binarized using the maximum entropy thresholding method implemented in ImageJ (Kapur et al. 1985). Projections from the MC and PC were detected in two separated color channels. The percent share of pixels containing ORN fibers from the MC and PC was calculated in relation to the total number of pixels containing fluorescent signal in either channel. This analysis was conducted separately for the dMOB and the vMOB.

To calculate the overlap of ORN axonal projections originating in the left and right olfactory epithelia (Fig. 5), we applied a median filter with a size of 10 pixels to the virtual two-color channel image stacks in ImageJ and subsequently binarized the image applying Huang’s fuzzy thresholding method (Huang and Wang 1995). We counted pixels containing signals in both color channels of the image for each image plane of the virtual image stack and calculated their percent share in relation to the number of all pixels containing any fluorescence signal. Separate analyses for dMOB and vMOB were conducted.

**Reconstruction and analysis of labeled projection neurons**

The morphology of projection neurons in the MOB labeled via electroporation was semi-automatically reconstructed from the image stack using Vaa3D (Peng et al. 2010; RRID:SCR_002609). Branching- and endpoints of the projection neurons were defined and translated into a hierarchical 3D tree-structure with the soma of the neuron as the root-point. Each segment of the neuron-tree has a single parent segment that it connects to. Each projection neuron connects to at least one olfactory glomerulus with a dendritic tuft. The number of tufts was determined using the DBSCAN algorithm.
Fig. 2 MC axonal projections gradually replace PC fibers in the vMOB during metamorphosis. New PC neurons innervate the dMOB. (a) Labeling of ORNs in the olfactory epithelia of MC (green) and PC (magenta) using different fluorophore-coupled dextrans via sparse cell electroporation. Dotted lines indicate the boundaries of the sensory epithelia. Close-ups show single bipolar ORNs extending their dendrite into the nasal cavity. Asterisks highlight the axons. (b–b’’) Tracings of axonal projections in the vMOB of tadpoles during different developmental stages (indicated by numbers in the panels). During premetamorphosis (b), the first ORN axons originating in the newly forming MC reach the glomerular layer (green). In prometamorphic animals (b’), both MC (green) and PC (magenta) axons are innervating glomeruli in the vMOB. During metamorphosis proper (b’’), the vMOB is solely innervated by axons originating in the MC (green), the newly formed dMOB only from PC fibers (magenta). Dotted lines indicate the outline of glomerular projections in the vMOB. The close-up shows axonal terminals of MC fibers in the glomeruli of the vMOB. (c) Scheme of innervation shift in the vMOB and newly formed connections to the dMOB (top). During premetamorphosis, the majority of vMOB projections originate in the PC (magenta), while at the end of metamorphosis, almost all axonal projections to the vMOB originate in the MC (green). The plot on the right shows the same data for the dMOB, which is only innervated by PC axons throughout development. Behavioral assay

Tadpoles of different developmental stages (stages 47–59) were placed in a 1-l water tank, which was separated into two areas by a dividing wall along approx. half of its length (Fig. 4). All areas were freely accessible to the tadpoles. Tadpoles were left to swim without stimulus application for a 2 h habituation period, and the average time they spent per visit to the two areas at either side of the dividing wall was recorded. After the habituation period, 5 ml of an amino acid mixture (100 µM at the application entry point at a speed of 2 ml/min) was applied through a gravity feed to one of the two areas, while a control stimulus (5 ml water) was simultaneously applied on the other side. The average time the tadpoles spent in the amino acid and water control area per visit was recorded for 20 min after their first visit to either area using EthoVision tracking software. Tadpoles that did not enter either side within 40 min after stimulus application were not included in the analysis.

Statistics

Averaged data are presented as mean ± standard deviation. A least-squares based polynomial regression curve of third-degree was fitted through the vMOB/dMOB volume data. A linear regression using the RANSAC (Random sample consensus) algorithm (scikit learn, RRID:SCR_002577; Pedregosa et al. 2011) was used to analyze the left/right projection overlap in the dMOB. Statistical significance was tested using a Mann–Whitney U test. Behavioral data are presented as median values of all experimental animals, and significance was assessed using Wilcoxon signed-rank test for paired data.

Results

The dMOB expands drastically during early metamorphosis

In premetamorphic larvae (up to stage 54), the olfactory epithelium in the PC innervates the vMOB (Fig. 1a, left). After metamorphosis is completed (stage 66), the PC epithelium connects to a newly formed dorsal target area (dMOB; magenta) and the de novo formed MC epithelium innervates the vMOB (green, Fig. 1a, right). We have monitored the stage-by-stage changes of ORN axonal projections to glomeruli in the MOB using fluorophore-coupled wheat germ agglutinin (WGA) tracing (Fig. 1b) and calculated their projection volumes in relation to the overall projection volume (Fig. 1c).

In premetamorphic tadpoles (stages 49–54), ORN axonal projections on the ventral side of the MOB are clearly discernable (green shaded area in Fig. 1b), while only a few axonal projections in the dMOB are visible (magenta, Fig. 1b). At this stage in development, the two MOB hemispheres are clearly separated. During prometamorphosis (stages 55–58) and metamorphosis proper (stages 59–65), the vMOB axonal projections only slightly increase in size, while the dMOB shows a more significant volume increase (Fig. 1b, middle and bottom). Around stages 53/54, the dMOB fuses at the midline and forms a single dorsal projection field.

During premetamorphosis, the projections in the vMOB occupied 64 ± 16% and in the dMOB 36 ± 16% of the entire axonal projections in the MOB (n = 5 animals, Fig. 1c). The relative volume of the vMOB progressively decreases to 40 ± 6% during metamorphosis (n = 7) and 35 ± 4% during metamorphosis proper (n = 6). Inversely, the dMOB grows to occupy 64 ± 4% of the entire MOB projection volume in the late metamorphic group. The best fit model for our data was a polynomial curve of third degree (least squares method, $R^2 = 0.9$, Fig. 1c). The magenta curve in Fig. 1c shows a steep increase in the relative volume of the dMOB from less than 20% at stage 50 to 50% around the end of premetamorphosis (intersection points of the two regression curves, Fig. 1c). Subsequently, the dMOB percentage is rising steadily but with a smaller slope until reaching between 60 and 70% in the late metamorphic stages.

The innervation of the vMOB dynamically shifts from the larval PC to the MC until metamorphic climax

While the glomerular structures of the dMOB are formed de novo, the vMOB undergoes major transformation processes during metamorphosis. We sparsely labeled ORNs in the newly forming MC (green, Fig. 2a) and the PC (magenta, Fig. 2a) and imaged their respective axonal projections in the MOB (Fig. 2b–b’). The ORNs labeled were bipolar neurons with a long dendritic shaft on the apical side of the epithelium and an axon leaving the epithelia on the basal side to join the olfactory nerve (asterisks, Fig. 2a). A single axon originating in the MC reaching the vMOB is found in a tadpole representative for premetamorphosis (green, Fig. 2b). Most ORN axons innervating glomeruli in the vMOB originated in the PC (magenta). In a metamorphic animal of stage 55, the majority of axonal projections still originates in the PC, while a few MC fibers can be seen (Fig. 2b’). At stage 62, the innervation shift is completed, with all axonal projections to the vMOB originating in the MC. Correspondingly, the newly forming dMOB only contains axons originating from the PC (Fig. 2b”).
During premetamorphosis (n = 4 animals), 95 ± 5% of the total innervation of the vMOB originates in the PC (Fig. 2c). A major shift occurs in prometamorphic stages (n = 5). Initially (stage 55/56), approx. 70% of the projections originate in the PC, while this value drops to around 30–40% in animals of stage 58. ORN projections from the MC are around 60–70% at the end of prometamorphosis. The vMOB in later metamorphic animals is innervated mostly by MC axons (82 ± 27%, n = 5). Around the time of metamorphic climax (stage 60/61), the majority of PC fibers in the vMOB of the premetamorphic stages is replaced by new ORN axons from the MC. Contrastingly, the dMOB is only innervated by PC axons across all developmental stages (97 ± 4%, n = 14 animals, Fig. 2c, right plot).

**Two parallel odor processing streams remain stable during rewiring of the vMOB**

ORN axonal projections from the PC epithelium to glomeruli in the vMOB are gradually replaced by MC projections during metamorphic remodeling. To determine whether this significant rewiring affects odor processing and whether the odor map remains unchanged, we loaded the ORN axons with a calcium-sensitive dye and imaged changes in fluorescent signal in their axonal projections upon stimulation with different odorant mixtures. We first applied a mixture of all odorant mixtures as a positive control and Ringer’s solution without odorants as a negative control, then the three individual odorant mixtures (amino acids, bile acids, amines) and forskolin (fsk), an activator of the adenylate cyclase and in consequence of the cAMP-dependent second messenger pathway.

Figure 3a shows the spatial distribution of regions responding to odorants (blue) and forskolin (yellow) in the vMOB of a prometamorphic (Fig. 3a, stage 57, above) and a metamorphic (stage 59, below) animal. For an approximate 3D representation of the responding regions, we split the entire vMOB (right images, Fig. 3a) into ventral (left images) and dorsal (middle images) halves. In the ventral halves of the vMOB of both animals, laterally located glomeruli did not respond to forskolin and exhibited transient calcium increases upon stimulation with odorants (Fig. 3a, blue). The majority of glomeruli in the medial portion of the ventral vMOB responded to forskolin application (Fig. 3a, yellow) and some regions additionally responded to the odorant mixtures (blue and yellow overlay). In the dorsal halves of the vMOBs of both animals, forskolin-responsive regions are not confined to the medial side, but were distributed across the entire span of the vMOB. This spatial response pattern was consistent across the 11 analyzed vMOB hemispheres from 8 different animals, and unchanged between prometamorphic (n = 6 vMOBs, 4 different animals) and metamorphic animals (n = 5 vMOBs, 4 different animals).

We analyzed a total of 270 responding regions and examined their tuning profiles and locations in the vMOB (Fig. 3a′–a‴‴, b). Responding regions varied significantly in size (average 770 ± 1264 µm²). We measured the relative position along the medial–lateral and anterior–posterior axis. Based on these positions, we estimated the probability density function along the two spatial axes to compare between the spatial distribution of forskolin-responsive (Fig. 3a′–a‴‴; orange; fsk +) and forskolin-non-responsive...
regions (blue; fsk-). We estimated the 2D probability density separately for the ventral (Fig. 3a’) and dorsal halves (Fig. 3a’’) of all vMOBs (including pro- and metamorphic animals) to add the third spatial dimension to the analysis. Additionally, we compared the probability densities between prometamorphic (Fig. 3a’’) and metamorphic (Fig. 3a’’’) samples (including both ventral and dorsal halves) to monitor possible changes during metamorphic remodeling.

The data showed that regions responding to forskolin and consequently using cAMP as second messenger (fsk +) are generally distributed more medially and anteriorly, with the area of highest estimated density visible in dark orange/brown. Forskolin-non-responsive regions (fsk-) are instead distributed more laterally and posteriorly (area of highest estimated density in dark blue). These general locations for the peak of the density distributions hold true for both the ventral and dorsal halves of the vMOBs (Fig. 3a’, a’’). In total, regions also or only responding to forskolin make up 43% in the ventral parts of pro- and metamorphic animals. In the dorsal part of the vMOBs, forskolin-responsive regions make up 87% (prometamorphic animals) and 80% (metamorphic animals).

Overall, these results strongly suggest that the segregation into two major odorant processing streams in the vMOB of tadpoles remains intact and unchanged even during the major metamorphic rewiring processes. Since these experiments solely highlight odor representation on the glomerular level, we next wanted to examine odor responses on a behavioral level to ascertain their functional stability during metamorphosis.

### Tadpoles of different developmental stages show behavioral response to amino acids

We performed a behavioral choice assay using tadpoles of different metamorphic stages up to metamorphic climax to assess their behavioral response to amino acid stimulation in a choice tank (Fig. 4a). During the habituation period, tadpoles showed no inherent preference to spend more time per visit in either side of the tank (premetamorphic tadpoles: median 13 s in area 1 and 13 s in area 2; n=9 animals, Fig. 4b; prometamorphic/ metamorphic tadpoles: median 14 s in area 1 and 12 s in area 2; n=9, Fig. 4b’). After habituation, tadpoles were simultaneously presented with water control and an amino acid application, and the average time they spent per visit in the water area (area 1), and the amino acid area (area 2) was recorded (Fig. 4b, b’). Amino acids have been well characterized as a major group of waterborne odors in several aquatic vertebrates (Sorensen and Caprio 1998; Syed et al. 2017) and have been shown to elicit behavior in *Xenopus* tadpoles (Terni et al. 2017). Tadpoles preferred to spend more time per visit in the amino acid area over the water control area (premetamorphic tadpoles: median 23 s in the amino acid area, 10 s in the control area, n=9, Fig. 4b; prometamorphic/metamorphic tadpoles: median 78 s in the amino acid area, 15 s in the control area, n=9, Fig. 4b’). Our results suggest that tadpoles are generally able to detect the presence of amino acids even during the substantial rewiring of the vMOB.

### Incoming ORN axons in the dMOB cross the midline and form a single projection area

While the neuronal network in the vMOB is rewired and ORN axons originating in the PC are replaced by new MC fibers, the dMOB network only starts to form during...
metamorphosis. We traced the ORN axons originating in the left and the right olfactory epithelium (both PC and MC) separately using two different fluorophore-coupled dextrans introduced by bulk electroporation and found several differences in the network structure between the vMOB and the dMOB (Fig. 5). Figure 5a shows the 3D depictions of ORN axonal projections traced in a pre-, pro-, and metamorphic animal. The images on the left and on the right show the same specimens in a ventral and dorsal view, respectively.

In the vMOB, the axons coming in from the left and right olfactory nerve project to two vMOB projection fields that are spatially separated at the interhemispheric midline (highlighted by the white dotted lines in the left images, Fig. 5a). The general outline of the glomerular projections in the vMOB remains constant throughout metamorphosis and only slightly increases in overall volume. Contrastingly, the first axonal projections reach the dMOB around stage 50 (Fig. 5a, top right) and project towards the interhemispheric midline. Until the onset of metamorphosis, the incoming fibers from both olfactory nerves have formed a single projection area around the midline, which grows until the end of metamorphic development. (Fig. 5a, right). During metamorphosis and metamorphosis proper, the hemispheres of the dMOB projections are not clearly separated anymore since axons cross the midline from both sides, frequently innervating glomeruli on the contralateral side. This feature of the dMOB becomes even more apparent when looking at sparse cell labeling (inset, Fig. 5a). Among the ORN axons crossing to the contralateral side, we found some axons only connecting to the ipsilateral or contralateral side, but some axons bifurcating and innervating glomeruli on both sides of the midline.

To quantify the positions of incoming ORN axons from the left (magenta, Fig. 5) and right epithelia (cyan), we counted pixels containing fluorescence signal from the ORN axons of the two epithelia along the left–right axis of the vMOB (Fig. 5b) and dMOB (Fig. 5b'). In the vMOB, the pixel count curves have symmetrical peaks on both sides of the interhemispheric midline (at approx. 80% of the distance to the edges; asterisks, Fig. 5b), while in immediate proximity to the midline, no pixels containing fluorescence signal could be counted. This pattern did not change from earlier stages (50–56; n = 4 animals) to later stages (57–66; n = 9) during metamorphosis. In the dMOB (Fig. 5b'), on the other hand, the symmetrical peaks were located closer to the midline, at approx. 15% (asterisks, Fig. 5b'), while in immediate proximity to the midline, no pixels containing fluorescence signal could be counted. This pattern did not change from earlier stages (50–56; n = 4 animals) to later stages (57–66; n = 7) during metamorphosis. In the dMOB (Fig. 5b'), on the other hand, the symmetrical peaks were located closer to the midline, at approx. 15% (asterisks) of the distance to the edges; asterisks, Fig. 5b'), while in immediate proximity to the midline, no pixels containing fluorescence signal could be counted. This pattern did not change from earlier stages (50–56; n = 4 animals) to later stages (57–66; n = 7) during metamorphosis. In the dMOB (Fig. 5b'), on the other hand, the symmetrical peaks were located closer to the midline, at approx. 15% (asterisks) of the distance to the edges; asterisks, Fig. 5b'), while in immediate proximity to the midline, no pixels containing fluorescence signal could be counted. This pattern did not change from earlier stages (50–56; n = 4 animals) to later stages (57–66; n = 7) during metamorphosis.

We further quantified the percent share of innervation overlap relative to the total projections in animals of different stages for the vMOB (Fig. 5c, white dots) and dMOB (Fig. 5c, black dots). The average overlap of the right and
During metamorphosis, ORN axons from the left and right olfactory epithelia form a single dMOB projection field with increasing bilateral innervation overlap. (a) Images of ORN axonal projections in the vMOB (left images, ventral view) and the dMOB (right images, dorsal view) in a pre-, pro-, and metamorphic animal. Projections from the left (magenta) and right (cyan) olfactory epithelia (both PC and MC) were traced with two different fluorophore-coupled dextran dyes (Alexa Fluor 488 and 594 dextrans) via electroporation. White dotted lines indicate the outlines of ORN axonal projections. While the left and right projections in the vMOB are clearly separated, the dMOB progressively fuses around the midline. The insert in the middle shows a close-up of sparsely labeled ORN axons crossing the midline (vertical dotted line) innervating contra- and ipsilateral glomeruli in the dMOB. (b, b') The number of pixels containing fluorescence signal from the ORN projections from the left (magenta) and right (cyan) were counted at each position along the left–right axis, separately for the vMOB (b) and the dMOB (b'). The thin lines represent individual animals and the bold lines the mean of all animals belonging to the two presented developmental groups (stages 50–56 and 57–66). The x-axis is scaled from the outermost right edge to the outermost left edge of axonal projections in the vMOB and mirrored around the midline in the dMOB, with 0 being the interhemispheric midline. In the vMOB (b), pixels around the midline did not contain fluorescence signal from ORN axons of either of the two epithelia, while in the dMOB (b'), pixels around the midline contained signal from axons from the left and right epithelia. The asterisks highlight the position with the highest count of pixels containing signal of axons from the left (magenta) or right (cyan). The maxima are close to the midline in the dMOB of both developmental groups. (c) The overlapping volume of axonal projections from the left and the right relative to the entire ORN axonal projection volume was calculated for tadpoles of different developmental stages and separately for the vMOB (white dots) and the dMOB (black dots). While the vMOB projections have no overlapping volume, the innervation overlap in the dMOB increases during metamorphosis. A RANSAC regression line was fitted through the data. (d) A close-up of the projections around the midline in the dMOB shows that single glomerular structures get input from both left and right olfactory epithelia (indicated by the magenta and cyan arrowheads, respectively). A anterior, D dorsal, dMOB dorsal main olfactory bulb, MET metamorphosis proper, ON olfactory nerve, P posterior, PRE premetamorphosis, PRO prometamorphosis, V ventral, vMOB ventral main olfactory bulb.

Projection neurons in the vMOB (n = 18 neurons, Fig. 6a, c) and dMOB (n = 16, Fig. 6b, d) share some general morphological features. Both groups have one or multiple primary dendrites (filled arrowheads in Fig. 6c, d) originating from the soma (white asterisks in Fig. 6) and terminating in highly branched dendritic tufts connecting to one or multiple glomeruli (Fig. 6a, b–b’’). A representative projection neuron with a single tuft in the right vMOB is shown in Fig. 6a, and a multi-tufted neuron in the dMOB in Fig. 6b. The tufts of neurons in the vMOB get synaptic input only from ipsilateral ORN projections (cyan projections in Fig. 6a), multiple tufts of a single projection neuron in the dMOB often project to both hemispheres, possibly integrating synaptic ipsilateral and contralateral ORN input (cyan and magenta in Fig. 6b). In addition to the dendrites receiving input from the dendritic tufts, most cells also have secondary dendritic branches with blunt endings and basal neurites (empty arrowheads, Fig. 6). Figure 6 c and d show reconstructions of representative projection neurons in the vMOB and dMOB that connect to a different number of glomeruli (white dotted circles).

From the reconstructions, we extracted several descriptors for the projection neurons (Supplementary video 1) and compared the measurements of neurons labeled in the vMOB and the dMOB (Fig. 6e). The tuft-soma distance along the dendrites (for cells with multiple tufts, the distance was averaged) was significantly longer in the dMOB cells (323 ± 96 µm) compared to the vMOB cells (230 ± 70 µm; p = 0.0046, Fig. 6e). Projection neurons in the vMOB and dMOB connected to an average of 1.7 ± 0.8 and 2.6 ± 1.1 dendritic tufts (p = 0.043), respectively, with an average tuft volume of 7679 ± 8208 µm³ and 2435 ± 5410 µm³ (p = 0.0003). We classified neurite branches along two axes into primary (originating in the soma) or secondary (branching off from primary or other secondary branches; Supplementary video 1) as well as dendritic/tufted (connected to the tufts) or basal neurites (not connected to the tufts). Neurons in the vMOB had 1.2 ± 0.5 primary-tufted dendrites and 1.7 ± 1 primary-basal neurites. The dMOB neurons exhibited significantly more of the former (1.9 ± 0.7; p = 0.0003) and a similar number of the latter (1.3 ± 1.4, Fig. 6e). The count of secondary-tufted dendrites was similar among the two groups (vMOB 3.9 ± 2.1, dMOB 3.8 ± 3.4) while the dMOB cells had more secondary-basal branches (7.1 ± 2.7) compared to the vMOB (4.4 ± 2.7; p = 0.004).

The most apparent difference between the two neuronal populations is the share of uni- and multi-tufted cell morphologies (Fig. 6f, barplots). Of neurons labeled in the vMOB, 55.6% are uni-tufted (gray, Fig. 6f), while only a single uni-tufted cell has been found in the dMOB (6.25%).
The bi- and tri-tufted neurons both make up 22.2% of the vMOB population (yellow in Fig. 6f). In the dMOB, the projection neurons maximally had five tufts. The biggest share of the population was bi-tufted and tri-tufted cells with 50% and 31.25%, respectively (orange in Fig. 6f). In the dMOB (grey; left, n = 12; three or more, n = 11; boxplots Fig. 6f), combining both neurons from the vMOB and the dMOB. Uni-tufted neurons had the greatest tuft volume (12,711 ± 8921 µm³; Fig. 6f, middle), significantly larger than the average tuft volume of the multi-tufted cells (bi-tufted: 2246 ± 2911 µm³, p = 0.001; three or more tufts: 946 ± 600 µm³, p = 0.0002). Inversely, the mean dendritic distance between tuft and soma increased with a higher number of tufts, measuring 211 ± 60 µm in uni-tufted, 281 ± 93 µm in bi-tufted, and 330 ± 93 µm in cells with three or more tufts (Fig. 6f, below).

As an additional descriptor for all multi-tufted cells, we measured the average spatial distance between two tufts of a cell as an estimate of spatial span of the neuron. Tufts of bi-tufted neurons were on average 146 ± 93 µm apart, with a maximum distance of 325 µm, while we measured 128 ± 74 µm for neurons with three or more tufts. Comparing all multi-tufted projection neurons in the vMOB (n = 8) and dMOB (n = 15) showed that the inter-tuft distance is significantly bigger in the dMOB (178 ± 73 µm; p = 0.0003) compared to the vMOB (62 ± 32 µm). Inversely, the volume of multi-tufted neurons in the vMOB was bigger than in the dMOB (2500 ± 2671 µm³; 1157 ± 1836 µm³; p = 0.008).

In summary, the projection neurons in the dMOB develop multiple small dendritic tufts, which receive input from spatially distant glomeruli, while at least half of the vMOB neurons have a single larger tuft receiving input from only one glomerulus.

**Discussion**

**ORN projections from the PC and MC form two distinct subsystems during metamorphosis**

During metamorphosis, the main olfactory system of most amphibians must undergo a complete transformation to adapt to the terrestrial lifestyle of the adult frog. In the case of *Xenopus*, the aquatic main olfactory epithelium of the tadpole transforms into a bimodal system consisting of the MC epithelium, associated with detection of waterborne odors, and the PC epithelium dedicated to aerial olfaction. This is supported by evidence showing that the larval PC and the adult MC — similar to the olfactory epithelium of fishes — both possess ciliated and microvillous ORNs (Hansen et al. 1998; Hansen and Zielinski 2005) and a similar set of olfactory receptors expressed (Amano and Gascuel 2012; Syed et al. 2013, 2017) that are tuned to detect waterborne odors such as amino acids (Syed et al. 2017). The postmetamorphic PC, on the other hand, expresses receptor genes more closely related to the mammalian receptors responsive to volatile odors (Freitag et al. 1995, 1998).

The projections of the ORNs in adult *Xenopus* towards their glomerular targets in the MOB have been described based on their lectin binding pattern (Key and Giorgi 1986; Hofmann and Meyer 1991; Franceschini et al. 1992). Fibers coming from the adult MC were found to be soybean-agglutinin positive and innervate the ventrolateral MOB, while the “aerial-fibers” from the PC were soybean-agglutinin negative and projected into the dorsomedial MOB (Hofmann and Meyer 1991; Gaudin and Gascuel 2005). In a thorough study of ORN projection fields in the MOB during development and metamorphosis, Gaudin and Gascuel describe that the dMOB (called PF9) in their study increases significantly in size (28 times increase) between stage 50 and 59, while the increase factor dropped to 1.4 in stages between 59 and 64 (Gaudin and Gascuel 2005). Our results confirm these findings (Fig. 1). We did not evaluate the absolute growth of the olfactory bulb structures but the changes in the percent share of the projection zones in the vMOB and...
the dMOB. We found that the biggest increase in the relative size of the dMOB happened until stages 55/56 with an increase from 0 to around 60% of the total volume, while the increase was only 10% from stages 57 to 64 (Fig. 1c). We additionally found that around stage 54, the projection fields of the dMOB and the vMOB already have approximately the same volume.

We investigated incoming fibers to the dMOB in animals throughout metamorphosis and found that input into the dMOB was solely originating from the PC. This is in accordance with prior studies (Reiss and Burd 1997a; Burd 1999). We did not find any fibers from the MC (Fig. 2c, right bar plot). The vMOB of the tadpoles is innervated by ORN axons from the PC. Around stage 52, the first axons from the newly formed MC reach the vMOB glomeruli (Reiss and Burd 1997a; Burd 1999). Reiss and Burd observed that from stages 52 to 58, PC axons could still be observed in the vMOB, while after that stage, the PC afferents have completely vanished from the vMOB, leaving only the MC axon terminals (Reiss and Burd 1997a).

We have quantified this dynamic shift in innervation in the vMOB and found that the relative innervation of the PC decreases gradually from stage 52 to around stage 61 (Fig. 2c, left plot). We still observed some PC axons after the onset of metamorphic climax (stage 58), even if by that time in the development, vMOB glomeruli are already majorly innervated by incoming MC ORN axons. Our data also are in accordance with results showing a peak in cellular apoptosis in the PC around stage 58 and later again around 62 (Dittrich et al. 2016). Some ORNs in the PC projecting to the vMOB could still be present at stages 58–62, undergoing apoptosis during the second apoptotic peak around stage 62, later than proposed by Reiss and Burd (Reiss and Burd 1997a).

Dynamic innervation shift of the vMOB does not disrupt glomerular or behavioral responses to odorants

During the described rewiring process in the vMOB, it had been unclear whether the glomeruli retain their larval functionality, if the odorant response pattern is reorganized, or if they temporarily lose a clear functional pattern. We imaged odorant induced response profiles of glomeruli in tadpoles up to stage 61 in the “water bulb” of Xenopus laevis and found that the extensive fiber replacement shows little effect on the coarse spatial organization of odorant responses in the vMOB. Odorant mediated responses can be recorded in the glomeruli of the vMOB up until the metamorphic climax, and their location within the glomerular cluster does not change significantly (Fig. 3). Our data suggest that replacement of ORN projections from the larval PC by new ORN projections originating in the MC happens gradually, without interrupting the spatial configuration and responsiveness of glomeruli in the vMOB. Similarly, behavioral responses to amino acids persisted at least until the metamorphic climax (Fig. 4). This implies an intact functional connection between the vMOB and higher downstream brain centers.

A recent study in the semiaquatic bullfrog Lithobates catesbeiana using electro-olfactography (EOG) showed a reduced electrophysiological response to spirulina extract — a food stimulus — as well as to a single amino acid (L-alanine) in metamorphic animals. Similarly, the behavioral preference for spirulina decreased during the metamorphic climax (Heerema et al. 2020). The authors of this study hypothesized that this decrease could mirror the temporary cessation of feeding behavior displayed by many anuran tadpoles during the metamorphic climax (Hourdry et al. 1996; Heerema et al. 2020). Alternatively, the reduced response to spirulina could stem from an ontogenetic shift to a terrestrial lifestyle in the bullfrog and a decrease in responsiveness to aquatic cues such as spirulina.

Even though we observed fewer odorant responsive regions in the metamorphic group when compared to the prometamorphic group, we did not see a complete cessation of olfactory responsiveness up to animals of stage 61. Also, metamorphic animals still showed behavioral responses to amino acids. Since Xenopus remains fully aquatic after metamorphosis is completed, it is likely, that there is less or no reduction of functionality in the water-smelling system during metamorphic climax, compared with species that change their lifestyle. This idea is further supported by a recent study showing that the glomerular clusters in the water bulb of Dendrobates tinctorius, a terrestrial frog species, seem gradually reduced until postmetamorphosis, when compared to the vMOB in Xenopus (Weiss et al. 2020a).

In tadpoles of Xenopus laevis, the spatial organization of odorant responses in the main olfactory epithelium and the MOB have been extensively studied (Manzini and Schild 2003, 2010; Gliem et al. 2013; Syed et al. 2017), but little to no functional imaging data exists for the metamorphic and postmetamorphic stages. In a comprehensive study from the epithelium to the MOB of tadpoles, it was shown that the MOB projections can be subdivided into two parallel processing streams (Gliem et al. 2013). Putatively microvillous ORNs projecting to the lateral glomeruli have a cAMP-independent second messenger pathway (Manzini et al. 2002; Manzini and Schild 2003) and are mostly responsive to amino acids (Gliem et al. 2013). The medial stream relies on the canonical cAMP-dependent pathway instead and is most probably formed by ciliated ORNs (Gliem et al. 2013). It was hypothesized that the lateral stream could be linked to ORNs expressing vomeronasal type 2 olfactory receptors (V2Rs) expressed in the lateral main olfactory epithelium of the larvae (Gliem et al. 2013; Syed et al. 2013, 2017). The expression pattern of the V2Rs and the response pattern to amino acids
gradually shifts to the adult MC during metamorphosis (Syed et al. 2017).

We show that the segregation between the lateral forskolin-non-responsive/cAMP-independent pathway and the forskolin-responsive/cAMP-dependent medial pathway is retained until stage 61 tadpoles (Fig. 3). Forskolin-induced calcium transients (Fig. 3a, orange) are missing in the ventrolateral glomerular cluster. Glomeruli in this part of the vMOB are instead responsive to odorant stimulation, particularly to stimulation with amino acids (blue). Our results also show that the cAMP-independent pathway is restricted to the ventral parts of the vMOB, while dorsal glomeruli are forskolin-responsive/cAMP-dependent.

It is notable that many responsive regions analyzed in this study only responded to forskolin, but not to any of the applied odorants. Based on previous experiments in Xenopus larvae (Gliem et al. 2013), we assume that these regions are responsive to different odorant groups, which were not individually applied in the present study. We also observed forskolin-induced responses in dMOB glomeruli in some of the animals, which complies with the idea of exclusively ciliated ORNs using the cAMP pathway projecting to this region of the MOB (Hansen et al. 1998). Future functional experiments using airborne odorants will have to examine the odor tunings of these ORNs.

Odorant receptor molecules themselves are thought to be a main determinant factor for ORN axonal targeting in the MOB in vertebrates (Feinstein and Mombaerts 2004; Mombaerts 2006). Since the MC expresses the same olfactory receptors as the larval PC epithelium (Amano and Gascuel 2012; Syed et al. 2017), it seems likely that the vMOB odor map also remains constant. Axon targeting mechanisms in the vMOB of Xenopus are likely to differ from the targeting in the dMOB since it relies on different odorant receptor families. Additionally, axon targeting does not seem to be restricted to the ipsilateral hemisphere since ORN fibers cross extensively over the midline. To date, no odorant map of the dorsal projections is available. To our knowledge, it is also unclear whether the dMOB of anurans is functionally organized symmetrically or whether ORN axons expressing a given receptor in the left and right PC project their axons to a single glomerulus.

The fusion of the olfactory bulb is not exclusive to anurans

The fused dMOB is not a feature exclusive to the anurans. It has also been described in some fishes and bird species (Nieuwenhuys 1966). It has been studied in more detail in passeriform birds (Huber and Crosby 1929; Yokosuka et al. 2009a, b; Corfield et al. 2015). However, in birds, the fusion on the gross anatomical level does not seem to relate to a functional overlap. In the Japanese Jungle Crow, it was shown that even though the olfactory bulb appears as one single mass, the olfactory nerves project separately to the left and right glomerular layer, with no significant left–right overlap (Yokosuka et al. 2009a). In contrast, the morphological results in the present study (Fig. 5), as well as electrophysiological studies in ranid frogs (Jiang and Holley 1992a), show a significant overlap between the ORN axon projections.

It is generally assumed that the relative size of the olfactory bulbs is correlated with the importance of olfactory capability across vertebrates (Corfield et al. 2015; Yopak et al. 2015). Among birds, the Passeriformes only possess a very small olfactory bulb in relation to the whole brain size (Corfield et al. 2015), suggesting a relative loss of reliance on their sense of smell. This is partially explained by the fact that these birds, especially the corvids, have evolved higher cognitive functions (Emery 2006; Corfield et al. 2015). Their small, fused olfactory bulb could thus be a sign of evolutionary degeneration of olfactory function. In anurans, the fused olfactory bulb has been described in different species (Hoffman 1963; Ebbesson et al. 1986; Scalia et al. 1991; Jiang and Holley 1992a), independently of their habitat and the degrees to which they rely on olfaction. It seems thus unlikely that the fusion of the olfactory bulb can be interpreted as a sign of olfactory degeneration in the anurans as well. It could rather add another level of bilateral information processing and possibly serve an ecological function, e.g., in spatial orientation (see below).

The evolutionary absence of the fused olfactory bulb in most vertebrates suggests that it is a derived evolutionary feature in both birds and frogs rather than an ancestral trait. Also, the close sister clade of the anurans, the salamanders, have two separated olfactory bulbs (Eisthen and Polese 2007). We thus propose a different origin of this feature and a putatively different function in the various animal groups, which remains to be explored.

Projection neurons in the vMOB and the dMOB are morphologically different

The morphology of the primary projection neurons in the olfactory bulb has been extensively studied in a variety of vertebrates (for review, see Dryer and Graziadei 1994; Nieuwenhuys 1966). Mammalian projection neurons are divided into mitral and tufted cells, with further subtypes being distinguished (Nagayama et al. 2014). Mitral cell somata are generally bigger in size and located more caudally, tufted cells are smaller and their somata are located closer to the glomerular layer (Mori et al. 1983; Macrides et al. 1985; Dryer and Graziadei 1994; Nagayama et al. 2014). In amphibians, it is still debated whether the population of projection neurons in the MOB can be subdivided...
(Laberge 2008). Morphological (Scalia et al. 1991; Jiang and Holley 1992b) and electrophysiological studies (Jiang and Holley 1992a) in adult ranid frogs propose a similar subdivision into tufted-like and mitral-like projection neurons in anurans as well.

In the present study, we tackled the question of whether the projection neuron populations in the vMOB (water system) and the dMOB (air system) of the aquatic *Xenopus* are morphologically different. It has been described for amphibians, reptiles, and fishes (Dryer and Graziadei 1994; Imamura et al. 2020), that projection neurons possess multiple primary dendrites that terminate in glomerular tufts and a variable number of secondary dendrites without tufts (Nieuwenhuys 1966; Scalia et al. 1991; Dryer and Graziadei 1994). We found that the number of secondary dendrites was comparable for cells in the vMOB (3.9 ± 2.1) and the dMOB (3.8 ± 3.4), which also is comparable to quantifications in ranid frogs (between 1 and 6) (Jiang and Holley 1992b), salamanders (0–5; Laberge, 2008), rabbits (2–5; Mori et al. 1983), rats (2–9; Dryer and Graziadei 1994; Orona et al. 1984), and hamsters (1.7–4.7; Macrides and Schneider 1982). Interestingly, the cells in the dMOB had a higher number of primary dendrites originating in the soma than vMOB cells, which mostly exhibit a single primary dendrite. This could enable dMOB cells to integrate independent dendritic input in the cell soma, while vMOB somata only receive a single dendritic input.

While the single primary dendrite of mammalian mitral/tufted cells in the MOB connect to a single glomerulus, projection neurons of earlier diverging vertebrates often innervate multiple glomeruli (Nieuwenhuys 1966; Dryer and Graziadei 1994; Nezlin et al. 2003). In the population analysis of projection neurons in ranid frogs, around 50% of examined neurons were found to be connected to a single glomerulus, ~30% were bi-glomerular, and 20% innervated more than two glomeruli (Jiang and Holley 1992b). This distribution is quite close to the counts we obtained in the vMOB (56% uni-, 22% bi-, 22% tri-glomerular; Fig. 6f). Interestingly, the number of glomeruli innervated by a single ORN axon in anurans also follows a similar distribution across different species and developmental stages (tadpoles 41% uni-glomerular, 59% multi-glomerular; juveniles: 50% uni, 50% multi-glomerular; Weiss et al. 2020b). It is still unclear if there could be a functional correlation between the different types of these distributions.

The projection neuron population in the dMOB is almost exclusively multi-tufted, with very small tuft volumes and longer distances between somata and tufts as well as between tufts (Fig. 6f). Generally, we noted that tuft volumes were bigger in uni-tufted-cells compared to multi-tufted cells, while distances were shorter in uni- than multi-tufted cells. A recent study in zebrafish suggested that the presence of uni- and multi-glomerular projection neurons hint towards the coexistence of distinct odor processing logics (Braubach and Croll 2021). The authors hypothesize that uni-glomerular projection neurons are primarily associated with glomeruli narrowly tuned to specific odors, eliciting specific behavioral responses (Yabuki et al. 2016; Dieris et al. 2017; Wakisaka et al. 2017). Multi-glomerular neurons, on the other hand, are associated with smaller glomeruli, possibly implicated in integrative odor processing of stimuli like bile acids or amino acids (Braubach and Croll 2021). Interestingly, a similar relationship between smaller glomeruli and multi-glomerular connectivity can also be observed in the completely unrelated locust olfactory system (Ignell et al. 2001).

Based on our data, we propose that the vMOB of *Xenopus* displays a coexistence of distinct wiring logics based on uni- and multi-tufted projection neurons, similar to what was shown in zebrafish (Braubach and Croll 2021). In contrast, the dMOB seems to be primarily associated with multi-glomerular projection neurons, which are possibly involved in integrative odor coding. In the light of the zebrafish data noted above, *Xenopus* could have some hardwired behavioral responses based on specific aquatic cues processed via the uni-glomerular system in the water bulb, while volatile odors could generally be processed in a combinatorial way. Additionally, the fact that the dMOB is a single unpaired structure and projection neurons connect to glomeruli in both hemispheres suggests that this system also integrates information from the left and the right olfactory epithelia. This seems to add another level of information integration to the detection of volatile odorants in the frogs.

**Putative ecological and behavioral relevance of the dMOB**

The presence of a well-developed system to sample airborne odorants seems counterintuitive in a fully aquatic frog. It has, however, been reported that *Xenopus* move overland mostly in search of other water bodies or food (Du Plessis 1966; Measey 2016). It has also been suggested that olfactory cues might play a role in overland orientation and migrations (Savage 1965). In the present study, we show how the neuronal circuit of the dorsal “air-bulb” in *Xenopus* differs from the ventral “water bulb” and most other vertebrate MOBs. The bilateral innervation of both ORNs and projection neurons gives it a high degree of integrative power. The importance of integration of bilateral sensory information has been shown for other sensory systems, but its role in olfaction has only been shown in rare instances (Catania 2013). Among anurans, the fusion of the two MOB hemispheres seems to be an ancestral trait with so far unknown function (Ebbesson et al. 1986; Scalia et al. 1991; Eisthen and Polese 2007). The anuran dMOB could be a primary olfactory center integrating odorant information from...
the left and right nose in individual, bilaterally innervated glomeruli or by multiple tufts of individual projection neurons. This could, e.g., facilitate the overland spatial orientation of *Xenopus*. Odorant-guided orientation and homing behavior is widespread in anurans. However, little is known about the neuronal structures involved (reviewed in Weiss et al. 2021). It is intriguing to think that the special input integration in the dMOB could be part of a spatial integration center used in orientation behavior.
