KEYWORDS: beta 2 microglobulin; biomarkers; chronic kidney disease of unknown etiology; heavy metals; Sri Lanka

INTRODUCTION

Chronic kidney disease of unknown etiology (CKDu) is an emerging form of CKD that predominantly affects working-age adults belonging to agricultural communities living in discrete geographic areas. Disease hotspots have been identified in several countries, including El Salvador, Nicaragua, Guatemala, Mexico, India, Egypt, and Sri Lanka. Despite its widespread distribution, the main clinicopathological features of the disease are similar among the different communities.

In Sri Lanka, CKDu is prevalent in the north-central region and the most affected communities are involved in paddy farming. The prevalence of the disease in this region range from 6% to 15%. Similar environmental, socioeconomic, and occupational risk factors for CKDu are prevalent in other areas of Sri Lanka, specifically among the sugarcane and paddy-farming communities living in the south-eastern dry zone. Nevertheless, these populations have not been a common focus of epidemiological studies on CKDu.

Although the exact etiology of CKDu is yet to be explained, it is considered a disease of multifactorial origin primarily resulting from environmental factors. Renal damage can progress even in the absence of continuous exposure to the risk factors. Therefore, community screening is of utmost importance in the detection and management of CKDu. The conventional markers, serum creatinine (sCr), and urine albumin to creatinine ratio (uACR), are not sensitive and specific enough for the diagnosis of CKD or CKDu in their asymptotic early stages. On the contrary, novel markers such as urinary β2 microglobulin (uβ2M), could provide better specificity and sensitivity in the early diagnosis.

A cross sectional study was conducted in 6 selected Grama Niladhari divisions located within the Butalla Divisional Secretariat in Moneragala district in Sri Lanka (Supplementary Figure S1 and S2) to assess the prevalence of CKD and CKDu, the value of uβ2M as a biomarker in the early diagnosis of CKD or CKDu, and to investigate the association of heavy metals such as cadmium, lead, and arsenic with CKD or CKDu.

RESULTS

Of the 352 individuals included, 194 (55.1%) were males. The median age was 47 years (interquartile range 36–57; Range = 12–83). In addition, 81% were farmers with the majority involved with either paddy or sugarcane cultivation or both (Supplementary Table S1). Deep (36.6%) and shallow (38.6%) wells were the main sources of drinking water with only 15.6% having access to tap water. Approximately two-thirds of the study population have used pesticides (67.4%) or fertilizer (67.7%). Of the participants, 26.7%, 25.8%, and 39.8% were involved with alcohol consumption, smoking, and betel chewing, respectively.
Twenty-seven (7.7%) had diabetes and 31 (8.8%) had hypertension. In addition, 47 (13.4%) had CKD with 2.6%, 1.4%, 4%, 3.1%, 0.9%, and 1.4% in CKD stages 1, 2, 3A, 3B, 4, and 5, respectively. Among the individuals with CKD, 6 (12.7%) had diabetes and 11 (23.4%) had hypertension. Suspected CKDu cases represented 30 of 47 (63.8%) of the total CKD cases. The suspected CKDu prevalence within the study population was 30 of 352 (8.5%). There was a male predominance (73.3%) in the suspected CKDu population (Chi-squared test; $P = 0.0003$).

Median urinary cadmium and lead excretion was significantly higher among individuals with suspected CKDu compared to individuals without CKD (Figure 1) (Supplementary Table S2). No such increase in the median urinary cadmium and lead excretion was...
observed among individuals with CKD presumed to be secondary to diabetes or hypertension (non-CKDu). There was a progressive increase in the median urinary cadmium excretion from the individuals without CKD, to individuals with CKD (non-CKDu), and to individuals with suspected CKDu (Kruskal-Wallis statistic = 9.646, \( P = 0.008 \)) (Figure 1). There was no significant difference in median urinary arsenic excretion between individuals with suspected CKDu, CKD (non-CKDu) and without CKD (Supplementary Table S2). There was a significant negative correlation of eGFR with urinary cadmium excretion (Spearman \( r = -0.19 \), confidence interval \([CI] -0.3 \text{ to } -0.07, P = 0.001 \)) (Figure 2a) but not with urinary arsenic or lead excretion.

Median u\( \beta_2 \)M level was significantly elevated among individuals with suspected CKDu compared to individuals without CKD (153.9 mg/g creatinine vs. 20.4 mg/g creatinine, \( P < 0.0001 \)). u\( \beta_2 \)M performed well in discriminating individuals with suspected CKDu from those without CKD with an AUC-ROC value of 0.790 (95% CI 0.689–0.891) (Supplementary Figure S3). Nevertheless, both sCr and uACR performed better than u\( \beta_2 \)M in discriminating individuals with CKDu from those without CKD with AUC-ROC values of 0.854 and 0.861 respectively. u\( \beta_2 \)M levels were higher in CKD stages 3B to 5 compared to CKD stages 1, 2 and 3A (Supplementary Table S3). There was a significant positive correlation between u\( \beta_2 \)M level and urinary cadmium excretion (Spearman \( r = 0.32, P < 0.0001 \)) (Figure 2b).

Increased age (odds ratio = 1.07; 95% CI 1.04–1.10), lower body mass index (odds ratio = 0.87; 95% CI 0.79–0.96), betel chewing (odds ratio = 2.28; 95% CI 1.35–4.95) and tubular dysfunction, as defined by u\( \beta_2 \)M more than or equal to 300 mg/g (odds ratio = 9.40; 95% CI 3.58–24.63), were significantly associated with suspected CKDu (Supplementary Figure S4).

**DISCUSSION**

This study provides new evidence that CKDu is present in areas outside the traditional CKDu endemic areas in the country. There were significantly high levels of cadmium and lead in urine among individuals having suspected CKDu. Furthermore, urinary cadmium level had a significant negative correlation with the eGFR suggesting a possible cadmium associated kidney damage.

The urinary cadmium level is an indicator of total body burden of cadmium. The critical urinary cadmium level associated with renal injury is considered as 2 \( \mu \)g/g to 10 \( \mu \)g/g creatinine, which corresponds with a renal cortical cadmium concentration of approximately 150 \( \mu \)g/g to 200 \( \mu \)g/g renal tissue.\(^6\) Nevertheless, a more recent study has shown that even a lower urinary cadmium level of more than 0.5 \( \mu \)g/g creatinine could be associated with CKD.\(^7\) Therefore, cadmium exposure could be considered as a potential risk factor for CKD in our population.

We observed a significant correlation between urinary cadmium and u\( \beta_2 \)M level in the study population.
Similar observations have been made in other populations exposed to cadmium. 51–53 B2-microglobulin is a low molecular weight protein that is freely filtered by the glomerulus and almost completely reabsorbed and catabolized by proximal tubular cells. 8,9 Elevated levels of uβ2M suggest renal tubular damage and have been observed in the setting of nephrotoxin associated renal injury. 8,54 In a previous Sri Lankan study, significantly higher uβ2M levels were observed in CKDu subjects compared to the healthy individuals and uβ2M with a receiver operating characteristic-area under the curve value of 0.853 has shown a high sensitivity and a low specificity in diagnosing individuals with CKDu. 9

Although uβ2M performed well in discriminating individuals with CKDu from those not having CKD in our study, sCr and uACR performed better. Considering that both sCr and uACR are part of the criteria used to diagnose CKDu, assessing uβ2M against histopathological changes of CKDu would have given a more accurate in understanding of its true value as a biomarker in the diagnosis of CKD. Furthermore, uβ2M showed a significant positive correlation with the urinary cadmium excretion in our study, suggesting that it could be a useful biomarker in the setting of cadmium associated CKD.

One of the key limitations of the present study was the classification of CKD based on a single measurement of sCr and/or uACR, rather than 2 measurements 3 months apart as recommended by the KDIGO guidelines. It is also possible that some of the individuals classified as CKD due to hypertension or diabetes could actually be having CKDu.

Our study provides useful insights into the prevalence, distribution and risk factors of CKDu in a non-CKDu endemic area in Sri Lanka. It is clear that the disease is not limited to the traditional endemic areas of Sri Lanka, and is found in other parts of the country that share similar geographical, environmental, and socioeconomic characteristics to those of the north-central province. Our findings also support the possible association of CKDu with exposure to heavy metals, such as cadmium and lead. It also suggests that uβ2M could be used as a potential biomarker for early diagnosis of CKDu.

**ACKNOWLEDGMENTS**

We would like to convey our sincere thanks to all the participants, medical and technical staff and government officials of the study areas for their valuable cooperation throughout the study. We would also like to thank the International Society of Nephrology for providing the funding for the study.

**Funding**

The study was funded by a grant awarded to ESW under International Society of Nephrology Clinical Research Program (16-02-37).
