Abstract

We study the Peskin-Takeuchi S-parameter of holographic technicolor models. We present the recipe for computing the parameter in a generalized holographic setup. We then apply it to several holographic models that include: (a) the Sakai-Sugimoto model and (b) its non-compactified cousin, (c) a non-critical analog of (a) based on near extremal $AdS_6$ background, (d) the KMMW model which is similar to model (a) but with $D_6$ and anti-$D_6$ flavor branes replacing the $D_8$ and anti-$D_8$ branes, (e) a model based on $D_5$ branes compactified on two $S^1$s with $D_7$ and anti-$D_7$ probe branes and (f) the conifold model with the same probe branes as in (e). The models are gravity duals of gauge theories with $SU(N_{TC})$ gauge theory and with a breakdown of a flavor symmetry $U(N_{TF}) \times U(N_{TF}) \rightarrow U_N(N_{TF})$. The models (a), (c),(d) and (e) are duals of a confining gauge theories whereas (b) and (f) associate with non confining models.

The S-parameter was found to be $S=sN_{TC}$ where $s$ is given by $0.017\lambda_{TC}$, $0.016\lambda_{TC}$, $0.095$, $0.50$ and $0.043$ for the (a),(b),(c),(d), (f) models respectively and for model (e) $s$ is divergent. These results are valid in the large $N_{TC}$ and large $\lambda_{TC}$ limit. We further derive the dependence of the S-parameter on the “string endpoint” mass of the techniquarks for the various models. We compute the masses of the low lying vector technimesons.

1 Introduction

One of the most urgent questions in particle physics is the nature of the mechanism of electro-weak symmetry breaking (EWSB) and in particular the exact structure of the Higgs sector. One appealing class of models that may provide an answer to this question are Technicolor models. In these models a new sector of strongly interacting fermions known as techniquarks are added to the S.M instead of the scalar Higgs. This sector will now be responsible for the spontaneous chiral symmetry breaking ($\chi SB$) via a condensate in the TeV scale. The condensate, in a similar manner to ordinary QCD, is of a tecniquark anti-techiquark operator. The techiquarks transform under certain representation of the gauge group $SU(N_{TC})$. In these models the Higgs boson is a composite state of a techniquark and an anti-etchniquark so that the hierarchy problem is avoided. One of the most restricting demands of an EWSB model is that it should produce a small Peskin-Takeuchi S-parameter$^1$. This requirement comes from high precision electro-weak measurement. The S-parameter defined as

$$S = 16\pi [(\Pi_{33}'(0) - \Pi_{3Q}'(0))]$$

is restricted to be in the range of $S = -0.1 \pm 0.1$ $^{[1],[2]}$. A special feature of the S-parameter that causes it to stand out among the high precision measurements, is that by its very definition, the S-parameter is isospin-independent. Hence the S-parameter is insensitive to the exact details of the model by which it is extended to explain the quarks masses (extended technicolor) and other means and structures which could be added to the model to explain the breaking of the isospin symmetry.

The main problem in dealing with technicolor models and in particular in determining their corresponding S-parameter is the fact that like QCD they are based on a strong dynamics which is non-perturbative in the region of interest. The AdS/CFT correspondence which is by now a very well known auge/gravity duality provides a useful tool to translate a strongly coupled gauge system into weakly coupled gravity duals. This opens the opportunity to use this duality for describing technicolor models in terms of weakly coupled gravity. Indeed the authors of $^3$ proposed a holographic technicolor model which is based on the Sakai-Sugimoto model $^4$. The model is based on Witten's model$^5$ of the near extremal limit of $N_{TC} \ D4$ branes compactified on a circle. Into this background a pair $N_{TF} = 2$ of $D8$ and anti-$D8$ branes is incorporated as techiflavor probe branes. In the region that corresponds in the field theory to the UV, the model admits an $U(N_{TF} = 2)_L \times U(N_{TF} = 2)_R$ chiral symmetry which is spontaneously broken in the IR into a $U(N_{TF} = 2)_V$ symmetry. In $^3$, using the AdS/CFT dictionary, the

\footnote{1 For the derivation of the S-parameter its relation to electroweak measurement and the definition of the variables in this expression see section $^2$.}
expressions for the axial and vector currents in the boundary field theory where deter-
mined. From these one can easily calculate the expressions for the vacuum polarization
and their derivatives which then determine the S- parameter. In fact as was discussed in
\[3\] there is a direct way as well as a sum-rule method to compute this parameter.

The goals of the this paper were threefold, first to generalize the construction \[3\] to a
wide class of models that reduces to a five-dimensional effective action of its techniflavor
gauge fields. Second, to apply this construction to certain concrete holographic models,
in particular with or without confinement and spontaneous $\chi SB$ and to determine their
S-parameter as well as the low lying vector technimesons. Third to determine the general
properties of holographic models and to compare between the holographic estimate of
the S-parameter to phenomenological estimation of the S-parameter based on scaled up
version of QCD.

We start with a five dimensional effective action derived from the DBI and CS actions
of the gauge fields on the probe branes. Assuming a background that depends only on the
radial coordinate, the most general action of this nature was written down. In analogy
to the derivation of \[3\] the expressions for the S-parameter in both the direct method
and the sum-rule method were derived. This recipe was then applied to the following
models:

- (a) The Sakai Sugimoto model \[4\] which is Witten’s model \[5\] generalized to include
D8 prob branes and admits confinement and $\chi SB$.

- (b) The uncompactified analog of the latter model. This model, which was analyzed
in \[6\], is dual of the NJL gauge system which does not admit confinement but still
exhibits spontaneous $\chi SB$.

- (c) A non critical analog of the Sakai Sugimoto model derived in \[7\], \[8\], \[9\] and
exhibits both confining and spontaneous $\chi SB$. This model consists of $N_{TF}$ pairs
of $D4 - \bar{D}4$ flavor brane probing a non critical $AdS_6$ background.

- (d) The KMMW model \[10\] which is also based on Witten’s model but with
$N_{TF} = 2 \, D6 - \bar{D}6$ techniflavor probe branes. The model admits confinement and
a spontaneous breaking of global flavor symmetry which is not a chiral symmetry

- (e) A holographic model \[?\] based on the near extremal limit of D5 branes com-
 pactified on two circles with $D7 - \bar{D}7$ flavor barnes. The model is confining and
$\chi SB$ is spontaneous.

- (f) The Klebanov-Witten conifold model with $D7 - \bar{D}7$ flavor branes \[12\], \[13\]. This
model is conformal before adding the flavor branes but still admits spontaneous
flavor $\chi SB$. 

2
We found that model (e) fails to serve as a candidate for Technicolor/Higgs sector since it has a divergent S-parameter. In the rest of the models considered we found a positive S-parameter which is linear in $N_{TC}$ that is $S = s N_{TC}$. In models (c), (d) and (f) $s$ is just a numerical factor independent of $\lambda_{TC}$ where $\Lambda_{TC} = g_{TC}^2 N_{TC}$. However, in the Sakai Sugimoto model and its AHJK cousin $s$ was found to be linear in $\lambda_{TC}$ (see table (1)). Recall that the results are valid in the large $N_{TC}$ and large $\lambda_{TC}$ limit.

Holographic Technicolor was studied in recent years also in the following papers [14]. The paper is organized as follows: We start in section 2 with a brief review of the physics behind the Peskin-Takeuchi S,T and U parameters. This section is brought for the benefit of the readers which are not familiar with those parameters. Other readers can move directly to section 3. Section 3 is devoted to the determination of the S-parameter in holographic models. We derive the formulae for computing the parameter from a general holographic model reduced to five dimensions. This is done in both a direct method as well as a sum-rule approach. In section 4 we show the way the general result is implemented for the Sakai-Sugimoto model as was derived in [3] and we further derive in a qualitative way the dependence of the S-parameter on the string endpoint masses. In section 5 we repeat the steps of section 4 but for the uncompactified version of Sakai-Sugimoto model presented by AHJK in [6]. In section 6 we examine a holographic model derived in [8] which is a non-critical analog of the Sakai-Sugimoto model based on $N_{TF}$ pairs of $D4-\bar{D}4$ flavor brane probing a non critical $AdS_6$ background. Section 7 is devoted to analyzing the S-parameter of the KMMW model [10]. The model is based on Witten’s model with $D6-\bar{D}6$ flavor probe branes. In section 8 we discuss a holographic model [?] based on the near extremal limit of D5 branes compactified on two circles with $D7-\bar{D}7$ flavor branes. We then discuss in section 9 the S-parameter of a model based on the conifold with $D7-\bar{D}7$ flavor branes. We conclude in section 10 where we present the summary of the paper and our conclusion from this work.

\section{2 Peskin-Takeuchi parameters[1]}

In the standard model, the EWSB and fermion masses are explained by the existence of the Higgs scalar field which acquire a non zero VEV. The physics of the Higgs sector depends on four free parameters, the coupling constants $g'$ and $g$ of the $U(1)_Y$ and $SU(2)_L$ respectively, $v$ the VEV of the Higgs field and its mass $m_h$. We can express certain observable quantities via these parameters such as

$$m_W = g \frac{v}{2} ; \quad m_Z = \frac{v}{2} \sqrt{g'^2 + g^2} ; \quad e = \frac{g g'}{\sqrt{g'^2 + g^2}} ; \quad G_f = \frac{1}{\sqrt{2} v^2} \quad (2)$$
We used three parameters to define four observable quantities so there is a hidden relation among them which is independent of the value of the parameters in the Lagrangian. Such a relation can be constructed for example by using the different definition of the weak mixing angle in terms of observable quantities such as:

$$s^2 = \sin^2 \theta_w = \frac{g'^2}{g'^2 + g^2} = 1 - \frac{m_W^2}{m_Z^2}$$

$$\sin 2\theta_0 = \left(\frac{e}{\sqrt{2}G_f m_Z^2}\right)^{1/2}$$

Another useful definition is constructed from the polarization asymmetry of $Z$ decays into left and right electrons

$$A_{LR} = \frac{\Gamma(Z \rightarrow \bar{e}_L e_L) - \Gamma(Z \rightarrow \bar{e}_R e_R)}{\Gamma(Z \rightarrow \bar{e}_L e_L) + \Gamma(Z \rightarrow \bar{e}_R e_R)} = \frac{(\frac{1}{2} - s_*)^2 - s_*^2}{(\frac{1}{2} - s_*)^2 + s_*^2}$$

These three different definition of the weak mixing angle coincide at tree level

$$\sin^2 \theta_w = \sin^2 \theta_0 = s_*^2$$

but their loop corrections are different. Subtracting them from each other or taking their ratios produces what is known as zeroth order natural relation which means a relation which doesn’t depends on the parameters of the Lagrangian. Hence, these relations are free of any UV divergencies coming from counter terms (since these only alters the parameters of the Lagrangian), and so the only quantum corrections they receive are finite and can be considered as predictions of the quantum structure of the theory. In light of (6) we can easily construct the following zeroth order natural relations:

$$c^2 - c_0^2 = s_0^2 - s_*^2 ; \quad s_*^2(q^2) - s_0^2 ; \quad s^2 - s_*^2(q^2)$$

where we used the definitions

$$c^2 = 1 - s^2 = \cos^2 \theta_w = \frac{m_W^2}{m_Z^2} ; \quad s_0^2 = \sin^2 \theta_0 ; \quad c_0^2 = \cos^2 \theta_0$$

Another useful zeroth order natural relation we shell use is the ratio of charged to neutral-current amplitudes denoted by $\rho_*(0)$, and is equal to one at tree level. Now, we would like to estimate the radiative corrections to these relations, and hopefully to divide them into standard model ones and to those coming from the technicolor sector which supposedly give the true descriptions of the Higgs sector. There are many kinds of loop corrections to these zeroth order natural relations, in addition to the corrections to the vector boson
propagator, there are vertex corrections, box diagrams, and diagrams with real photon emission. In strongly interacting technicolor models the techniquarks do not couple directly to the leptons and at low energies do not appear in the final states, the only place where the new physics going to enters is through corrections to the vector boson propagator via its vacuum polarization where they appear in loops of techniquark and anti-techniquark pairs. Otherwise the techniquarks are not observed at low energy, hence these corrections are called 'oblique'. We note that in general, loop contributions are not gauge invariant one by one, but rather their sum is, but since these are the only contributions involving the techniquarks their gauge invariance is self evident. As we noted earlier our goal is to separate the radiative corrections coming from the new physics from that of the standard model, if we assume that \( m_f \ll m_Z \) (\( m_f \) is the mass scale of the fermions at the outer legs), then we can ignore the vertex corrections and box diagrams since these are suppressed by additional factor of \( \frac{m_f^2}{m_Z^2} \) relatively to the oblique correction. So we are left with the problem of separating the new physics contributions to the vacuum polarization from the SM’s. The experimental data that we are trying to fit comes from physics at energy scales between \( \Lambda_{QCD} \) to the TeV scale. In this range of energies the QCD is weakly coupled while the techniquarks are still in the strong coupling regime. Hence we can use perturbation theory to estimate the quarks contributions to the vacuum polarization amplitude of the gauge fields but we cannot do so for the techniquarks. The one loop SM oblique corrections to (7) are given by:

\[
\begin{align*}
 s^2 - s_0^2 &= -\frac{3\alpha}{16\pi(c^2 - s^2)} \frac{m_f^2}{m_Z^2} + \ldots \\
 s^2 - s^*_s &= -\frac{3\alpha}{16\pi s^2} \frac{m_f^2}{m_Z^2} + \ldots
\end{align*}
\]

Now, denoting \( \Pi_{IJ} \) as the correlators of the \( I \) and \( J \) currents of \( SU(2)_L \times U(1)_Y \), where only the contributions coming from the new physics are taking into account, then after some algebra we obtain the following form for the radiative corrections to (7) due to the Technicolor sector:

\[
\begin{align*}
 c^2 - c_0^2 &= s_0^2 - s^2 = -\frac{e^2 c^2}{s^2(c^2 - s^2)m_Z^2} \left[ \Pi_{33}(m_Z^2) - 2s^2\Pi_{3Q}(m_Z^2) \\
 &- \frac{s^2}{c^2}\Pi_{11}(0) - \frac{c^2 - s^2}{c^2}\Pi_{11}(m_W^2) \right] + \frac{e^2 s^2 c^2}{c^2 - s^2} \left[ \Pi'_{QQ}(m_Z^2) - \Pi'_{QQ}(0) \right]
\end{align*}
\]

\(^2\)We note that the one loop vacuum polarization amplitude is proportional to \( \frac{m_f^2}{m_Z^2} \) where \( m_q \) is the mass of the fermion in the loop, so one only consider the top quark contribution.

\(^3\)Of course one should also consider the contributions coming from the physical Higgs boson, but since we are replacing this sector by the technicolor sector, it is omitted [15].
\[ s^2(q^2) - s_0^2 = \left[ \frac{e^2}{c^2 - s^2} \left[ \frac{\Pi_{33}(m_Z^2)}{m_Z^2} - 2s^2\Pi_{3Q}(m_Z^2) - \Pi_{11}(0) \right] - (c^2 - s^2)\frac{\Pi_{3Q}(q^2)}{q^2} \right] + \frac{e^2s}{c^2 - s^2} \left[ s^2\Pi_{QQ}(m_Z^2) - c^2\Pi'(0)_{QQ} + (c^2 - s^2)\Pi'_{QQ}(q^2) \right] \tag{11} \]

\[ \rho_*(0) - 1 = \frac{e^2}{s^2c^2m_Z^2} \left[ \Pi_{11}(0) - \Pi_{33}(0) \right] \tag{12} \]

Thus, we see that it is both possible and natural to isolate the radiative corrections due to new physics from those coming from the SM fields. If the new physics included in the vacuum polarization amplitude is associated with new heavy particles of mass scale \( m_{TC} \gg m_Z \), then we will see a rapid convergence of a Taylor expansion in \( q^2 \) of these amplitude. Thus it is natural to expand the \( \Pi_{IJ} \) in powers of \( q^2 \), neglecting the order \( q^4 \) and beyond:

\[
\begin{align*}
\Pi_{QQ}(q^2) & \approx q^2\Pi'_{QQ}(0) \\
\Pi_{3Q}(q^2) & \approx q^2\Pi'_{3Q}(0) \\
\Pi_{33}(q^2) & \approx \Pi_{33}(0) + q^2\Pi_{33}(0) \\
\Pi_{11}(q^2) & \approx \Pi_{11}(0) + q^2\Pi'_{11}(0)
\end{align*}
\]

There are six independent coefficient in \( \Pi_{IJ} \) but three linear combinations of them must cancel out since there are no UV divergences in \( \Pi_{IJ} \), \( \Pi_{33} \) and \( \Pi_{11} \) despite there are in the \( \Pi_{IJ} \). The remaining three are the following:

\[
\begin{align*}
S & \equiv 16\pi[\Pi_{33}'(0) - \Pi_{3Q}'(0)] \\
T & \equiv \frac{16\pi}{s^2c^2m_Z^2} \pi[\Pi_{11}(0) - \Pi_{33}(0)] \\
U & \equiv 16\pi[\Pi_{11}'(0) - \Pi_{33}'(0)]
\end{align*}
\]

Substituting \( S, T, U \) into \( \Pi_{IJ} \) yields:

\[
\begin{align*}
\frac{m_W^2}{m_Z^2} - c_0^2 & = \frac{\alpha c^2}{c^2 - s^2} \left[ -\frac{1}{2}S + c^2T + c^2 - s^2 \right] \tag{15} \\
s^2(q^2) - s_0^2 & = \frac{\alpha}{c^2 - s^2} \frac{1}{4}S - s^2c^2T \\
\rho_*(0) - 1 & = \alpha T
\end{align*}
\]

To summarize, we concluded that under the above assumptions the dominant radiative corrections to \( \rho_* \) comes from the vacuum polarization amplitudes, and these receive contributions from two sources, the standard model part given by \( \Pi_{IJ} \) which is fixed and
well known, and a part coming from a sector of new physics and are given by (15). According to (15), we have a three parameter description of the radiative corrections due to the technicolor sector, and since the quantities in the left hand side are all observable there are experimental bounds on the magnitude of these corrections! In this paper we focus on pure technicolor models without an extension that could produce isospin violation, in this case the $T$ and $U$ parameters are zero and we use the experimental bound on $S$ alone. These experimental bounds restricts $S$ to be in the range of $S = -0.1 \pm 0.1$.

The Peskin-Takeuchi S-parameter defined above in (14) can be also expressed as

\[ S = 16\pi[(\Pi'_{33}(0) - \Pi'_{3q}(0)) = -4\pi[\Pi'_V(0) - \Pi'_A(0)]] \]  

(16)

where $\Pi_V$ and $\Pi_A$ are define by

\[ i \int d^4xe^{-iqx}\langle J^a_V(x)J^b_V(0)\rangle = -\left(g_{\mu\nu} - \frac{q_\mu q_\nu}{q^2}\right)\delta^{ab}\Pi_V(q^2) \]

\[ i \int d^4xe^{-iqx}\langle J^a_A(x)J^b_A(0)\rangle = -\left(g_{\mu\nu} - \frac{q_\mu q_\nu}{q^2}\right)\delta^{ab}\Pi_A(q^2) \]

where $\mathcal{J}^a_V$ and $\mathcal{J}^a_A$ are the vector current and axial-vector current respectively. Using dispersive representation with delta function resonances these could be expressed by

\[ \Pi_V(-q^2) = \sum_n \frac{g_{V_n}^2 q^2}{m_{V_n}^2 (-q^2 + m_{V_n}^2)} \]

\[ \Pi_A(-q^2) = \sum_n \frac{g_{A_n}^2 q^2}{m_{A_n}^2 (-q^2 + m_{A_n}^2)} \]

It follows then that $S$ could be written as

\[ S = 4\pi \sum_n \left( \frac{g_{V_n}^2}{m_{V_n}^4} - \frac{g_{A_n}^2}{m_{A_n}^4} \right) \]  

(17)

where $m_{V_n/A_n}$ and $g_{V_n/A_n}^2$ are the masses and decay constants of the vector/axial-vector mesons of the confined phase of the Technicolor sector.

### 3 The holographic S parameter

The general holographic technicolor setup is similar to that of holographic QCD. It is based on a gravity background that admits confinement in the sense of an area-law

\footnote{Below we discuss also models without confinement or without chiral symmetry}
behavior of the Wilson line and a discrete spectrum with a mass gap of states dual to the techniglueballs. The background is characterized by a flux, typically associated with a RR form, denoted here by $N_{TC}$ which corresponds to the rank of the dual technicolor gauge group $SU(N_{TC})$. A set of $N_{TF}$ flavor probe $D_p$ branes is incorporated in this background. The worldvolume of the $D_p$ flavor branes includes the four dimensional space-time, the radial direction and a $p - 4$ non-trivial cycle. The physics of the flavor brane is determined by an action defined on the worldvolume of the probe branes that include a DBI term and a CS term

$$S_{TF} = S_{DBI} + S_{CS} = -T_p \int d^{p+1}\sigma e^{-\phi} \sqrt{-\text{det}(g_{ind} + F)} + T_p \int \sum_k C_k \wedge e^F$$  \hspace{1cm} (18)$$

where $T_p$ is the tension of the $D_p$ probe branes, $g_{ind}$ is the induced metric on those probe brane, $F = 2\pi l_s^2 \tilde{F} + B_{ind}$ where $F$ is the techniflavor field strength associated with $U(N_{TF})$ gauge symmetry and $B_{ind}$ is an induced $B$ field (if there is one) and $C_k$ is a $k$ RR form.

Since an important ingredient in the technicolor scenario is the spontaneous breaking of the technichiral symmetry, the flavor probe branes have to admit geometrically in the region dual to the UV flavor chiral symmetry of the form $U_L(N_{TF}) \times U_R(N_{TF})$ and in the IR a spontaneous breakdown of this symmetry to the diagonal subgroup $U_D(N_{TF})$. This requires an embedding profile of the form of a U shape. Examples of such a holographic setup are the well known Sakai Sugimoto model [4], its non-critical analog and the recently proposed model based on incorporating D7 flavor branes in the Klebanov Strassler model.

Integrating the DBI action over the $p - 4$ compact cycle expanding in powers of derivatives and gauge fields and keeping the lowest order one finds the following five dimensional YM action for $U(N_{TF})$ gauge fields.

$$S_{DBI} = -\frac{\kappa_p}{4} \int d^4x du [a(u) F_{\mu\nu} F^{\mu\nu} + 2b(u) F_{\rho \mu} F^{\rho \mu}]$$  \hspace{1cm} (19)$$

where $u$ indicates the radial direction, Greek indices are space-time indices, the contraction of indices is done with $\eta_{\mu\nu}$, $\kappa_p$, $a(u)$ and $b(u)$ are given by

$$\kappa_p \equiv -\frac{T_p(2\pi \alpha') V_{p-4}}{g_s}$$

$$a(u) \equiv g_s e^{-\phi} \sqrt{\text{det}(g_{ind})(g_{ind}^{\rho \rho})^2} \quad b(u) \equiv g_s e^{-\phi} \sqrt{\text{det}(g_{ind}) g_{ind}^{\rho \rho} g_{ind}^{\mu \mu}}$$  \hspace{1cm} (20)$$

and where we assumed that the induced metric is diagonal and $V_{p-4}$ is the volume of the compact cycle the probe brane wrap. The equations of motion associated with the
variations of $A_\rho$ and $A_u$ are given by

$$a(u)\partial^\mu F_{\mu\rho} + \partial^u (b(u) F_{u\rho}) = 0$$

$$\partial^\rho F_{\rho u} = 0$$

(21)

As was discussed above the geometrical realization of chiral symmetry implies that the probe is of a form of a U shape with two branches. Thus the profile is a double valued function of the radial coordinate, which generically is in the range $\infty \geq u \geq u_0$. It is useful to define a different coordinate $z$, $\infty \geq z \geq -\infty$ so that the boundary of one branch of the probe brane say the left one, is at $z = -\infty$ and the boundary of the right one is at $z = +\infty$. Expressed in terms of this coordinate the DBI action (19) takes the form

$$S_{DBI} = -\kappa_p \int d^4xdz \left[ \hat{a}(z) F_{\mu\nu} F^{\mu\nu} + \hat{b}(z) F_{\rho\sigma} F^{\rho\sigma} \right]$$

(22)

where

$$\hat{a}(z) = u'(z) a(u(z)) \quad \hat{b}(z) = \frac{b(u(z))}{u'(z)}$$

(23)

with $u'(z) = \frac{du}{dz}(z)$. It is clear that the corresponding equations of motion take the same form as (21) with $z$ replacing $u$ and $\hat{a}$ and $\hat{b}$ replacing $a$ and $b$. We continue our discussion here using the $u$ coordinates but obviously we can invert the analysis using a $z$ coordinate.

It is convenient at this point to choose the $A_u(x,u) = 0$ gauge. The rest of the gauge fields $A_\mu(x,u)$ are expanded in terms of normalizable non-zero modes and non-normalizable zero modes. In addition we divide the gauge fields into vector fields $V_\mu$ which are symmetric around $u_0$ (or under $z \leftrightarrow -z$) and axial vector fields $A_\mu$ which are antisymmetric. Upon further Fourier transforming the space-time coordinate $x^\mu \rightarrow q^\mu$ the expanded fields take the form

$$A_\mu(q,u) = V_\mu(q) \psi^0_{V}(u) + A_\mu(q) \psi^0_{A}(u) + \sum_{n=1} (V^m_\mu(q) \psi_{V_n}(u) + A^m_\mu(q) \psi_{A_n}(u))$$

(24)

The normalizable modes are the bulk gauge fields while the non-normalizable are by the gauge/gravity dictionary sources for boundary currents. In fact as was shown in [19] the gauge transformation that sets $A_u = 0$ requires that the zero modes include massless modes which are the Goldstone bosons associated with the spontaneous breakdown of the techniflavor chiral symmetry. These modes play obviously an important role in the
technicolor mechanism since they will provide the mass of the electroweak gauge bosons once part of the techniflavor symmetry is gauged.

In terms of this expansion the equations of motion (21) are

\[
\frac{1}{a(u)} \partial^u (b(u) \partial_u \psi_n(u)) = -m_n^2 \psi_n(u) \]

\[
\frac{1}{a(u)} \partial^u (b(u) \partial_u \psi_0(q^2, u)) = -q^2 \psi_0(q^2, u)
\]

(25)

where we have used for the normalizable modes \( \partial^\rho \partial_\rho V^\mu_n = q^2 V^\mu_n = m_n^2 V^\mu_n \) and where we have used \( \partial^\rho V^\mu_0 = 0 \) that follows from the equation of motion. These equations hold for both the vector modes \( \psi_{V_n} \) as well as the axial vector modes \( \psi_{A_n} \). Note that the eigenvalue problem (25) becomes first order o.d.e for \( m_n^2 = 0 \) and so have only one solution which is the odd one in accordance with the fact that the pions are pseudoscalars.

Plugging the decomposition (24) into (19) we find

\[
S_{F^2} = -\frac{\kappa_p}{4} \int d^4q du Tr \left( a(u) \left[ \sum_{n=1}^\infty \left[ |F_{\mu\nu}^V(q)|^2 \psi_{V_n}(u) + |F_{\mu\nu}^A(q)|^2 \psi_{A_n}(u) \right] 
+ |F_{\mu\nu}^0(q)|^2 \psi_0^V(u) + |F_{\mu\nu}^{A0}(q)|^2 \psi_0^A(u) + 2F_{\mu\nu}^V(q)F_{\mu\nu}^V(q) \psi_{V_n}(u) 
+ 2F_{\mu\nu}^{A0}(q)F_{\mu\nu}^{A0}(q) \psi_{A_n}(u) \right] 
- 2b(u) \left[ |V_0^V(q)|^2 (\partial_u \psi_0^V)^2 + |A_0^A(q)|^2 (\partial_u \psi_0^A)^2 \right. 
+ \left. \sum_{n=1}^\infty \left| V_n^V(q) \right|^2 (\partial_u \psi_{V_n})^2 + |A_n^A(q)|^2 (\partial_u \psi_{A_n})^2 \right] \right)
\]

(26)

To further reduce the action to four dimensions we have to normalize the \( \psi_{V_n} \) and \( \psi_{V_n} \) modes. This is done as follows Normalizing the gauge field as

\[
\kappa_p \int du a(u) \psi_{V_n} \psi_{V_m} = \delta_{nm}
\]

(27)

and the same for \( \psi_{A_n} \). Had we chosen to use the \( z \) coordinates the normalization condition would have same structure with \( \hat{a}(z) \) replacing \( a(u) \). The resulting 4d YM action reads

\[
S_{F^2} = -Tr \int d^4q \sum_{n=1}^\infty \left( \frac{1}{4} |F_{\mu\nu}^V(q)|^2 + \frac{1}{4} |F_{\mu\nu}^A(q)|^2 - \frac{1}{2} m_{V_n}^2 |V_n^V(q)|^2 - \frac{1}{2} m_{A_n}^2 |A_n^A(q)|^2 
+ \frac{1}{2} a_{V_n} F_{\mu\nu}^V(q) F_{\mu\nu}^V(q) + \frac{1}{2} a_{A_n} F_{\mu\nu}^A(q) F_{\mu\nu}^A(q) \right) + S_{\text{source}}
\]

(28)

where

\[
a_{V_n} = -\kappa_p \frac{b(u)}{m_{V_n}^2} \partial_u \psi_{V_n}|_{u=\infty}
\]

(29)
and the same for $a_{An}$ expressed in terms of $\psi_{An}$. We define $S_{source}$ to be the terms in (26) which involve only the source

$$\frac{\kappa_p}{2} \int d^4q \, d\mu(u) Tr \left\{ |V_\mu^0(q)|^2 (\partial_u \psi_y^0)^2 + |A_\mu^0(q)|^2 (\partial_u \psi_A^0)^2 + |F_{\mu\nu}^0(q)|^2 \psi_{y0}^2(u) + |F_{\mu\nu}^{A0}(q)|^2 \psi_{A0}^2(u) \right\}$$  \hfill (30)

Performing an integration by parts in the first term we find

$$\frac{\kappa_p}{2} \int d^4q \, d\mu(u) Tr \left\{ |V_\mu^0(q)|^2 \int d\mu \partial_u [\psi_y^0 b(u) \partial_u \psi_y^0] - \psi_y^0 \partial_u [b(u) \partial_u \psi_y^0] \right\}$$

$$= \frac{\kappa_p}{2} \int d^4q \, d\mu(u) |V_\mu^0(q)|^2 \left\{ [\psi_y^0 b(u) \partial_u \psi_y^0]_{u=\infty} + q^2 \int d\mu(u) (\psi_y^0)^2 \right\}$$ \hfill (31)

The last term cancels exactly the $|F_{\mu\nu}^0(q)|^2$ term in (30) and there is a similar cancelation for the axial gauge fields. Thus the leftover source term takes the form

$$S_{source} = -\frac{1}{2} Tr \int d^4q \left\{ a_{V0} |V_\mu^0(q)|^2 + a_{A0} |A_\mu(q)|^2 \right\}$$ \hfill (32)

where

$$a_{V0} = -\kappa_p b(u) \partial_u \psi_y^0(u, q^2)|_{u=\infty}$$ \hfill (33)

$$a_{A0} = -\kappa_p b(u) \partial_u \psi_A^0(u, q^2)|_{u=\infty}$$ \hfill (34)

where we have used the equations of motion and we have taken that $\psi^0|_{u=\infty} = 1$ for both the vector and axial vector zero modes.

The coupling between the source $V_0^0 (A_0^0)$ and the vector (axial) mesons fields can be read from (28) after the kinetic terms of the vector will be diagonalize, this is done by the transformation

$$\tilde{V}_\mu^n = V_\mu^n + a_{Vn} V_\mu^0 \quad ; \quad \tilde{A}_\mu^n = A_\mu^n + a_{An} A_\mu^0$$ \hfill (35)

Now the action in terms of the new fields is

$$S_F = -Tr \int d^4x \sum_{n=1} \left( \frac{1}{4} |\tilde{F}_{\mu\nu}^n(q)|^2 - \frac{1}{2} m_{Vn}^2 (\tilde{V}_\mu^n - a_{Vn} V_\mu^0) \right.$$

$$+ \frac{1}{4} |\tilde{F}_{\mu\nu}^{An}(q)|^2 - \frac{1}{2} m_{An}^2 (\tilde{A}_\mu^n - a_{An} A_\mu^0) \bigg) + \tilde{S}_{source}$$ \hfill (36)

where

$$\tilde{S}_{source} = -\frac{1}{2} Tr \int d^4q \left\{ a_{V0} |V_\mu^0(q)|^2 + a_{A0} |A_\mu(q)|^2 \right.$$  

$$+ \sum_n \left( a_{Vn} |F_{\mu\nu}^{Vn}(q)|^2 + a_{An} |F_{\mu\nu}^{An}(q)|^2 \right) \bigg\}$$ \hfill (37)
and we find that the decay constants are

\[ g_{V_n} = m_{V_n}^2 a_{V_n} = -\kappa_p b(u) \partial_u \psi_{V_n} \big|_{u=\infty} \]  

(38)

\[ g_{A_n} = m_{A_n}^2 a_{A_n} = -\kappa_p b(u) \partial_u \psi_{A_n} \big|_{u=\infty} \]  

(39)

Now we have assembled all the ingredients to determine the value of the holographic S parameter. As discussed in the previous section, this can be done in two different ways. In the first method we need to compute holographically the two point functions of the vector and axial vector currents. Using the AdS/CFT dictionary this reads

\[ -\Pi_V(q^2) \equiv \langle J^\mu_V(q^2) J^\nu_V(0) \rangle_{F.T} = \frac{\delta}{\delta V_0^\nu} \frac{\delta}{\delta V_0^\mu} S_{DBI} \big|_{V^0=0} = a_V^0(q^2) \]  

(40)

where \( V^0_\mu \) is the boundary value of the vector gauge field at \( u = \infty \). The same applies also for the axial vector correlator. Substituting (40) into (16) the holographic S-parameter reads

\[ S = -4\pi (\Pi'_V(q^2) - \Pi'_A(q^2))|_{q^2=0} = -4\pi \frac{\partial}{\partial q^2} (a_V^0(q^2) - a_A^0(q^2))|_{q^2=0} \]

\[ = -4\pi \kappa_p \left[ b(u) \frac{\partial}{\partial q^2} (\partial_u \psi_V^0(u, q^2) - \partial_u \psi_A^0(u, q^2)) \right] \big|_{q^2=0; u=\infty} \]  

(41)

The second method is based on inserting the decay constants (38) into the expression for the S parameter as sum over resonance given in (42), yielding

\[ S = 4\pi \sum_n \left[ (a_{V_n})^2 - (a_{A_n})^2 \right] = 4\pi (\kappa_p) b^2(u) \sum_n \left[ (\partial_u \psi_{V_n})^2 - (\partial_u \psi_{A_n})^2 \right] \big|_{u=\infty} \]  

(42)

Here we have used the gauge/gravity duality rules and derived the holographic form of the two expressions (redefinition) and (42) that were shown in the boundary field theory to be equivalent. In fact one can show directly in the gravity setup that the two expressions are equivalent. This was done in [3] for the sakai Sugimoto model but can be done in a similar way for the general setup discussed in this section. The issue of when a partial sum of a small number of low lying states is a good approximation to the full sum is discussed in [16].

The determination of the S-parameter follows from the solutions of the equations of motion (25). The latter, as will be seen in the following sections, depend on the profile of the probe brane and in particular on the point with minimal value of the radial direction.
This parameter relates to the “string endpoint mass” of the meson (technimesons in our case) which are defined as follows [17]

\[ m_{sep} = \frac{2}{\pi} \int_{u_\Lambda}^{u_0} \sqrt{-g_{tt}g_{uu}} du \]

(43)

This mass is clearly not the current algebra or QCD mass, and in fact it is also not the constituent mass of the meson. This mass can be thought of as

\[ m_{sep} = \frac{1}{2} (M_{meson} - T_{st} L_{st}) \]

where \( T_{st} \) is the string tension and \( L_{st} \) is the length of the string. The fact that it is not the QCD mass is easily determined from the fact that the pions associated with a probe brane profile with non trivial \( u_0 \) are massless. Thus this mass parameter is not related at all to the masses of particles running in the loops that determine the \( S \) parameter. Hence we should not expect the dependence of the \( S \) parameter to resemble that of the dependence of the QCD masses. Indeed as will be seen in the sections below the dependence on \( m_{sep} \) or on \( u_0 \) will be different in the various models studied and nor related the dependence on the QCD masses.

4 The Sakai Sugimoto model

The starting point of the holographic Technicolor Sakai Sugimoto model is Witten’s model [5]. The model describes the near extremal limit of \( N_{TC} D4 \)-branes wrapping a circle in the \( x_4 \) direction with anti periodic boundary condition for the fermions. Having in mind the use of the model as a holographic technicolor model, we use from the onset \( N_{TC} \) and below \( N_{TF} \) instead of \( N_c \) and \( N_f \) of the original model. In order to incorporate fundamental quarks in this model it was suggested in [4] to add to this background a stack of \( N_{TF} D8 \) branes and a stack of \( N_{TF} \) anti \( D8 \) branes. Assuming \( N_{TF} \ll N_{TC} \) the backreaction of the flavor probe branes can be neglected as was shown to leading order in \( \frac{N_{TF}}{N_{TC}} \) in [?]. The background which includes the metric the RR form and the dilaton is given by

\[ ds^2 = \left( \frac{u}{R_{D4}} \right)^{3/2} \left[ -dt^2 + \delta_{ij} dx^i dx^j + f(u) dx_4^2 \right] + \left( \frac{R_{D4}}{u} \right)^{3/2} \left[ \frac{du^2}{f(u)} + u^2 d\Omega_4^2 \right] \]

(44)

\[ F_4 = \frac{2\pi N_c}{V_4} \epsilon_4 , \quad e^\phi = g_s \left( \frac{u}{R_{D4}} \right)^{3/4} , \quad R_{D4}^3 = \pi g_s N_c l_s^3 , \quad f(u) = 1 - \left( \frac{u_\Lambda}{u} \right)^3 \]

where \( V_4 \) denotes the volume of the unit sphere \( \Omega_4 \) and \( \epsilon_4 \) its corresponding volume form. \( l_s \) is the string length and \( g_s \) is the corresponding string coupling. The techniflavor branes are placed in such a way that the compactified \( x_4 \) direction is transverse to them asymptotically. The manifold spanned by the coordinate \( u, x_4 \) has the topology of a cigar where its tip is at the minimum value of \( u \) which is \( u = u_\Lambda \). The periodicity of this cycle
is uniquely determine to be
\[ \delta x_4 = 2\pi R = 2\pi R \left( \frac{R_{D4}}{u_\Lambda} \right)^{1/2} = 2\pi R \tag{45} \]
in order to avoid a conical singularity at the tip of the cigar. We also see that the typical scale of the glueball masses computed from excitation around (44), is
\[ M_{gb} = \frac{1}{R} \tag{46} \]
The confining string tension in the model is given by [17]
\[ T_{st} = \frac{1}{2\pi \ell_s^2} \sqrt{g_{xx} g_{tt}} \Big|_{u=\Lambda} = \frac{1}{2\pi \ell_s^2} \left( \frac{u_\Lambda}{R_{D4}} \right)^{3/2} \tag{47} \]
Corresponding to \( u_\Lambda \) one defines the following mass scale
\[ M_\Lambda = \frac{1}{R} = \frac{3}{2} \frac{u_\Lambda^{1/2}}{R^3/2} \tag{48} \]
Naively one could assume that at energies below \( M_\Lambda \), the dual gauge theory is effectively four dimensional; however since the theory confines and develops a mass gap of order \( M_{gb} \sim M_\Lambda \) there is no real separation in mass between the confined four dimensional hadronic modes, like the glueballs and the Kaluza-Kleive excitations on the \( x_4 \) circle. As discussers in [5] in the opposite limit where \( \lambda_5 = g_5^2 N_c \ll R \) one can see from loop calculations that the scale of the mass gap is exponentially small compared to \( 1/R \) hence the theory does approach the \( 3+1 \) pure Yang-Mills theory at low energies. It is believed that there is no phase transition when varying \( \lambda_5/R \) interpolating between the gravity regime to pure Yang-Mills. For convenience we will use from here on the freedom to re-scale the \( u \) coordinate and set \( u_\Lambda = 1 \).

The flavor probe brane are space filling in all the direction except on the cigar where we need to find their classical curve. In this case the problem is reduce to an o.d.e for \( x_4 = x_4(u) \) that follows from the equation of motion associated with the DBI action of the \( D8 \) branes. In fact the general form of the profile can be determined even without the equations of motion. In the geometry of the cigar the flavor branes cannot end and hence they have to fold back and end asymptotically at \( u \to \infty \) again transverse to the \( x_4 \) direction. The solution of the equation of motion is found to be
\[ x_4(u) = \int_{u_0}^u \frac{du}{f(u)} \left( \frac{u}{R_{D4}} \right)^{3/2} \sqrt{\frac{f(u) u_\Lambda^8}{f(u_0) u_\Lambda^8} - 1} \tag{49} \]
where \( u_0 \) is a constant of integration which determines the lowest value of \( u \) to which the \( D8 \) branes extend to before folding back to the UV. Notice that this U shape with a tip
at \( u = u_0 \) generalizes the model of [4]. The interpretation of \( u_0 \), as the string endpoint mass was discussed in section (3). Since the orientation of the \( D8 \) was flipped while passing through \( u_0 \) it is actually a \( \bar{D}8 \) brane and so we have \( D8 - \bar{D}8 \) system. As was mentioned above a more natural way to look at this situation is that one begins with \( N_{TF} \) \( D8 \) located for \( u \to \infty \) at \( x_4 = x_4^{(L)} \) and \( N_{TF} \) \( \bar{D}8 \) brane at \( x_4 = x_4^{(R)} \) and finds that due to the classical equations of motion they join together at \( u = u_0 \). In the model of [4] \( x_4^{(L)} = 0 \) and \( x_4^{(R)} = \pi \). We see that the global \( U_L(N_{TF}) \times U_R(N_{TF}) \) chiral symmetry of the theory is spontaneously broken by the ground state down to \( U_V(N_{TF}) \). So, we got a gravity model whose dual gauge theory admits at low energies confinement and chiral symmetry is spontaneously broken. These two qualities are of great importance in QCD phenomenology and also in building technicolor models. An HTC model means we identify the gauge group as the technicolor \( SU(N_{TC}) \) and the quarks are techniquarks and the vector field fluctuation of the \( D8 \) branes are vector technimesons.

We now compute S-parameter associated with the technicolor model based on the generalized Sakai Sugimoto model by applying the two methods described in section (3). The action of the gauge fields is given by

\[
S_{F^2} = - \frac{T_8(2\pi\alpha')^2 V_{S_4} R_{D4}^2 \gamma^{1/2}}{4 g_s u_A^{1/2}} \int d^4 x d\mu \left\{ \left( \frac{\gamma}{u} \right)^{1/2} F_{\mu \nu}^2 + \frac{2 u^{5/2}}{R_{D4}^3 \gamma^{1/2}} F_{\mu \nu}^2 \right\}
\]

Using the general discussion of section (3), the model is characterized by

\[
\kappa_8 = \frac{T_8(2\pi\alpha')^2 V_{S_4} R_{D4}^2 \gamma^{1/2}}{g_s u_A^{1/2}} = \frac{g^2 N^2}{36\pi^2}, \quad a(u) = \left( \frac{\gamma}{u} \right)^{1/2}, \quad b(u) = \frac{u^{5/2}}{R_{D4}^3 \gamma^{1/2}}.
\]

where

\[
\gamma = \frac{u^8}{f(u)u^8 - f(u_0)u_0^8}
\]

Solving numerically equations (25) for the present case and plugging the results into (16) we reproduced the results of [3]. For the anti-podal configuration \( u_0 = u_A = 1 \)

\[
S = 19.66\kappa_{D8} = 19.66\frac{g^2 N^2}{36\pi^2} = 0.017\lambda_{TC} N_{TC}
\]

where \( \lambda = g^2 N_{TC} \). The authors of [3], used the values \( N_{TC} = 4 \) and \( \lambda_{TC} = 4\pi \) to compare the holographic computation with the results of [1]. This kind of comparison has to be taken with a grain of salt since the holographic result is valid in the limit of large \( \lambda_{TC} \) and large \( N_{TC} \).
For the general non anti-podal configurations we find that $S$ is growing linearly with $u_0$. Another useful results could be obtained from Weinberg sum rule

$$\Pi_A(0) = F_\pi^2 = (246\text{GeV})^2$$

where we assigned the techni-pion decay constant the value of the electroweak scale in order to reproduce the spectrum of the electroweak gauge bosons. Using (54) this gives

$$F_\pi^2 = a_{A0}(0) = -\kappa_{D8} R_{D4}^{-3} u^{5/2} \gamma^{-1/2} \partial_u \psi^0_A(u)|_{u=\infty}$$

Numerical integration of (25) gives

$$F_\pi^2 = a_{A0}(0) = 0.42 \kappa_{D8} M_{KK}^2 = 0.019 M_A^2$$

where like in [3] we choused to use the values $\lambda_{TC} = 4\pi$ and $N_{TC} = 4$. This set the Kaluza-Klein mass scale to $M_A = 1.8\text{TeV}$ and we can determine now the mass spectrum of the mesons. We find the first vector technimeson resonance to be $m_\rho \approx 1.5\text{TeV}$ and the techni-axial vector meson $m_{a_1} \approx 2.2\text{TeV}$ [3]. Actually, after the assignment of the Kaluza-Klein scale there are no more free parameter in the theory except $u_0$ which has no 4$d$ interpretation.

As we pointed out in the previous section, there is another way to to estimate the S-parameter by using the sum over hadronic resonance given in (42). Summing up to $n = 8$ we find

$$S_8 = -1\kappa_{D8} \approx -0.001 \lambda_{TC} N_{TC}$$

Thus the contribution from the eight lowest states is negative and very far from the result found above. This is in accordance with the statement made in section based on [16], that the higher KK modes do not decouple from the spectrum on this background and that $S_n$ for some finite $n$ does not produce a good approximation for $S$.

Next we want to study the dependence of the S-parameter on $u_0$. Using (41) for different values of $u_0$ we found numerically that $S$ tends to grow linearly with $u_0$. We will see this behavior in a more qualitative manner for large $u_0$ by using scaling argument on either one of (41) or (42). We will show how to apply this argument on the scheme given in (42) but we note that it could be applied easily the same to (41). We start by changing variable in (25) to $y = \frac{u}{u_0}$ and then we take the limit $u_0 \gg 1$, in this limit we find that

$$\gamma \rightarrow \tilde{\gamma}(y) = \frac{y^8}{y^8 - 1}$$
In this limit the action of the gauge field in (50) could be written as
\[
S_{F^2} = -\kappa_8 \left( \frac{u_0}{u_\Lambda} \right)^{1/2} \int d^4x dy \left\{ \left( \frac{\tilde{\gamma}}{y} \right)^{1/2} F_{\mu\nu}^2 + 2 \frac{u_0}{R_{D4}^3} y^{5/2} \tilde{\gamma}^{1/2} F_{\mu y}^2 \right\}
\]  
(59)
and (25) becomes
\[
y^{1/2} \tilde{\gamma}(y)^{-1/2} \partial_y (y^{5/2} \tilde{\gamma}(y)^{-1/2} \partial_y \tilde{\psi}_n(y)) = -\frac{m_n^2 R_{D4}^3}{u_0} \tilde{\psi}_n(y)
\]  
(60)
Since the left hand side of (60) is independent of \(u_0\), then so is the right one, and we find
\[
m_{Vn/An}^2 \sim \frac{u_0 R_{D4}^3}{R_{D4}^3}
\]  
(61)
Now doing the same manipulation on (38) we get
\[
g_{Vn} = -u_0^{3/2} \kappa_8 R^{-3} y^{5/2} \tilde{\gamma}^{-1/2} \partial_y \psi_{Vn}(y) |_{y=\infty}
\]  
(62)
we might conclude that
\[
g_{Vn/An} \sim \frac{u_0^{3/2}}{R_{D4}^3}
\]  
(63)
b ut since the normalization of the modes (27), is now taken to be:
\[
\kappa_8 \left( \frac{u_0}{u_\Lambda} \right)^{1/2} \int dy \left( \frac{\tilde{\gamma}}{y} \right)^{1/2} \tilde{\psi}_n(y) \tilde{\psi}_m(y) = \delta_{mn}
\]  
(64)
we need to take into account that
\[
\psi(u) = u_0^{-1/4} \psi(y)
\]  
(65)
Combining (62) and (65) we find
\[
g_{Vn/An} \sim \frac{u_0^{5/4}}{R_{D4}^3}
\]  
(66)
Now plugging (61) and (66) into (42) we find
\[
S_n \sim u_0^{1/2}
\]  
(67)
In the Sakai Sugimoto model the spontaneous breaking of the techniflavor symmetry is attributed to the U-shape configuration of the $D8-\bar{D}8$ branes. As was mentioned above this is a result of the cigar structure of the submanifold of the $(u,x_4)$ directions. It turns out that this is a sufficient condition for having a U-shape form but it is not a necessary condition. That is to say that there is a U shape solution even if $x_4$ is not compactified at all. Decompactifying the $x_4$ direction is achieved technically by simply substituting one instead of $f(u)$ in (118). This model was studied in [6], and the profile of the probe branes was found to be given by (49) only with $f(u) = 1$ and that the integral could be brought to the closed form

$$x_4(u) = \frac{1}{8} \left( \frac{R^3}{u_0} \right)^{1/2} \left[ B\left(\frac{9}{16}, \frac{1}{2} \right) - B\left(\frac{u_0^8}{u^8}; \frac{9}{16}, \frac{1}{2} \right) \right]$$

where $B(p,q)$ and $B(x,p,q)$ are the complete and in complete beta functions. The asymptotic separation between the $D8$ and $\bar{D}8$ branes $L$ is given by

$$L = \frac{1}{4} \left( \frac{R^3}{u_0} \right)^{1/2} B\left(\frac{9}{16}, \frac{1}{2} \right)$$

In terms of the dual field theory the model is in fact physically very different from the Sakai Sugimoto model. It is a gravity model dual to a non-confining gauge theory. Recall that the holographic expression of the string tension is given by (47) evaluated at the minimum value of $u$ [17] which for the present case is $u = 0$ and hence the string tension vanishes.

The effective five dimensional flavored gauge theory for the present case is identical to that of the Sakai Sugimoto model, namely, the characterization given in (51) applies also for the uncompactified model with the difference that now the function $\gamma$ is given by

$$\gamma = \frac{u^8}{u^8 - u_0^8}$$

The action of the gauge fields could be rescaled into the form

$$S_{F^2} = -\frac{T_8 (2\pi \alpha')^2 V_5 R_{D4}^{9/2}}{4g_s u_0^{1/2}} \int d^4x dy \left\{ \left( \frac{\gamma}{y} \right)^{1/2} F_{\mu\nu}^2 + 2 \frac{u_0}{R_{D4}^3 \gamma^{1/2}} y^{5/2} F_{\mu y}^2 \right\}$$

Unlike the situation in the compactified case of the previous section, in the AHJK model there is no compactification scale below which the theory becomes effectively 4d, so the definition of the 't Hooft coupling of the 4d gauge theory is not so clear.
Nevertheless, there are two scales in the problem that could be used to construct the 4d \('t\ Hooft coupling; \(L\) and \(\ell_s\). In the first case we set
\[
\lambda_4 = \lambda_{TC} = \frac{\lambda_5}{L} = \frac{g_sN_{TC}\ell_s}{L}
\] (72)

where \(\lambda_5\) is the \('t\ Hooft coupling of the five dimensional gauge theory. The asymptotic distance between the \(D8\) and \(\bar{D8}\) is given numerically by
\[
L \approx 0.72 \frac{R_{D4}^{3/2}}{u_0^{1/2}}
\] (73)

and we find:
\[
\kappa_8 = \frac{T_8(2\pi\alpha')^2V_{S_4}R_{D4}^{9/2}u_0^{1/2}}{4g_s} = \frac{0.72T_8(2\pi\alpha')^2V_{S_4}R_{D4}^6}{g_sL} = \frac{0.48\ell_s g_sN_{TC}^2}{(2\pi)^4L} = \frac{0.48\lambda_{TC}N_c}{(2\pi)^4}
\] (74)

Solving numerically the e.q.m of the non-normalizabe mode given in (25), and substituting it into (41) we find that the S-parameter is given by
\[
S_{AJHK} \approx 19.1\kappa_8 = .006\lambda_{TC}N_{TC}
\] (75)

and we note that the dependence on \(u_0/L\) is now hidden inside the definition of \(\lambda_{TC}\).\footnote{Note that the gravity description is only valid for \(\lambda_5 >> L\).}

Using \(\ell_s\) instead, the dimensionless ratio is \(\lambda_5/\ell_s\) and we find
\[
\tilde{\lambda}_{TC} = \lambda_5/\ell_s = g_sN_{TC}
\] (76)

so
\[
\kappa_8 = \frac{g_s^{1/2}N_c^{3/2}\sqrt{\pi}}{6(2\pi)^3} \left(\frac{u_0}{\ell_s}\right)^{1/2} = \frac{\sqrt{\pi}\tilde{\lambda}_{TC}N_{TC}}{6(2\pi)^3} \left(\frac{u_0}{\ell_s}\right)^{1/2} = 0.0012\left(\frac{u_0}{\ell_s}\right)^{1/2} \tilde{\lambda}_{TC}N_{TC}
\] (77)

And we find that the S-parameter is given by (for \(\frac{u_0}{\ell_s} = 1\))
\[
S_{AJHK} = .023\tilde{\lambda}_{TC}^{1/2}N_{TC}
\] (78)

6 Non critical \(AdS_6\) model

In the model discussed in the previous section and in all the models we will encounter in the following sections the flavor branes were wrapping certain non-trivial cycles on top of spanning the Minkovski space and the radial direction. In fact the wrapped dimensions have not played any role in the technicolor scenario and in particular in the determination
of the S parameter. This naturally calls for models without the wrapped cycle and in general with as less as possible extra dimensions. Models of this kind are the non-critical gravitational models. Such a model that may serve as a non-critical dual of QCD was proposed in [9]. This model is based on a non-critical SUGRA background presented in [8],[7] which can be viewed as the backreaction of $N_{TC}$ coincident D4 branes placed in flat 6d space with linear dilaton. In [9] the model was modified by introducing fundamental quarks via $N_{TF}$ D4 and anti-D4 prob branes.

The various fields in the background are:

$$ds_6^2 = \left(\frac{u}{R_{AdS}}\right)^2 dx_{1,3}^2 + \left(\frac{R_{AdS}}{u}\right)^2 \frac{du^2}{f(u)} + \left(\frac{u}{R_{AdS}}\right)^2 f(u)dx_4^2$$  \hspace{1cm} (79)

$$F_{(6)} = Q_c \left(\frac{u}{R_{AdS}}\right)^4 dx_0 \wedge dx_1 \wedge dx_2 \wedge dx_3 \wedge du \wedge dx_4$$  \hspace{1cm} (80)

$$e^\phi = \frac{2}{\sqrt{3Q_c}} \quad ; \quad f = 1 - \left(\frac{u_A}{u}\right)^5 \quad ; \quad R_{AdS}^2 = \frac{15}{2} \ell_s^2$$  \hspace{1cm} (81)

where $Q_c = \frac{N_{TC}}{2\pi}$ with $N_{TC}$ being the number of D4 branes, $x_4$ is taken to be periodic where to avoid conical singularity its periodicity is set to

$$x_4 \sim x_4 + \delta x_4 \quad ; \quad \delta x_4 = \frac{4\pi R_{AdS}^2}{5u_A}$$  \hspace{1cm} (82)

We also define $M_\Lambda$ as a typical scale below which the theory is effectively four dimensional:

$$M_\Lambda = \frac{2\pi}{\delta x_4} = \frac{5u_A}{2R_{AdS}^2} = \frac{u_A}{3}$$  \hspace{1cm} (83)

One should note that unlike in critical SUGRA models, in this model $R_{AdS}$ is a constant independent of $g_sN_{TC}$, hence the curvature is always of order one and there is no way to go to a small curvature regime.

Into this background a set of $N_{TF}$ pairs of D4–$\bar{D}4$ prob branes are placed in a similar manner as in the Sakai-Sugimoto model, namely they span asymptotically the coordinates ($x_0,...x_3,x_5$). In the corresponding brane configuration, one cannot separate the color and flavor branes, namely the strings that connect the two types of branes are necessarily of zero length, hence it is dual to a field theory system with chiral symmetry. The profile of the probe branes is determined by solving the equations of motion that follow from their DBI action. Unlike the critical case, here there is a priori an additional CS term on top of the DBI action (18) of the form $S_{CS} = T_4 \int P(C_5)$. However, for reasons given in [18] including the CS term yields unphysical results, hence from here on
we shall set the CS term to zero. Thus using only the DBI action the profile of the probe
branes is found to be

\[ x_{4,cl}(u) = \int_{u_0}^{u} \left( \frac{u'}{R_{AdS}} \right)^{2} f(u') \sqrt{u'^{10} f(u') - u_0^{10} f(u_0)} du' \]  

(84)

Again for convenience we define

\[ \gamma = \frac{u_0^8}{u^{10} f(u) - u_0^{10} f(u_0)} \]  

(85)

We also rescale u to set \( u_\Lambda = 1 \).

In terms of the general discussion of section (3), the model is characterized by

\[ \kappa_{nc} = T_4^{(nc)} (2\pi\alpha')^2 e^{-\phi} R_{AdS} = \sqrt{\frac{5}{2}} \frac{3 NTC}{16 \pi^3} \sim 0.0095 NTC \]

(86)

Once we obtained the solution for the non-normalizable mode by numerical integration
of (25) we plug it into the holographic definition of S (41), and got an estimation of S,
for the antipodal configuration \( u_0 = u_\Lambda = 1 \):

\[ S = 10.3 \kappa_{nc} = 0.095 N_{TC} \]  

(87)

The dependence of S on \( u_0 \) for \( u_0 > u_\Lambda = 1 \) is drawn in figure (1). It is obvious from the
figure that at large \( u_0 \) S is a constant independent of \( u_0 \). The asymptotic value it takes
is \( \frac{S}{\kappa_{nc}} \approx 6.54 \). This behavior will be derived below also qualitatively.

Next we would like to compute the S parameter using the sum rule formula of (42). To
compute \( S_8 \), the sum over first eight resonance, we need on top of the low lying masses
also the corresponding decay constants. These are determined by solving numerically
(38). Substituting the values of the masses and of the decay constants into (42) and
summing up to \( n = 8 \) we find

\[ S_8 = 8.96 \kappa_{nc} = 0.086 N_{TC} \]  

(88)

According to [16] it was anticipated that the higher KK modes will decouple from the
spectrum and that \( S_n \) for some finite \( n \) will produce a good approximation for S.
Non-critical model: In blue, $S_8$ vs. $u_0$.
In green, vector mesons (even modes) $m_n$ vs. $u_0$.
In red, axial vector mesons (odd modes) $m_n$ vs. $u_0$.

Figure 1: $S_8$ in the non critical model vs. $u_0$. The linearity of the vector (axial) mesons masses in $u_0$ could be seen from their dotted green (red) plots for the first 8 modes ($u_Λ = 1$).
For the general case $u_0 > u_\Lambda = 1$, the S-parameter seems to be almost independent of $u_0$ as could be seen in figure (1). In order to see the S-parameter dependence on $u_0$ in a more qualitative manner we repeat the scaling argument we used in section (4). By changing to the dimensionless variable $y = \frac{u}{u_0}$ we find that after taking the limit $u_0 \gg 1$ eq. (25) and (38) becomes

\begin{equation}
\tilde{\gamma} \gamma^{-1/2} \partial_y \left( y^2 \tilde{\gamma} \gamma^{-1/2} \partial_y \tilde{\psi}_n(y) \right) = -\frac{m_n^2 R_{AdS}^4}{u_0^2} \tilde{\psi}_n(y) \tag{89}
\end{equation}

\begin{equation}
-\kappa_{nc}(R_{AdS}^4)^{-1} y^2 \gamma -1/2 \partial_y \tilde{\psi}_{Vn}|_{y=\infty} = \frac{g_{Vn}}{u_0} \tag{90}
\end{equation}

where we noted that in this limit

\begin{equation}
\gamma \rightarrow \tilde{\gamma}(y) = \frac{y^8/u_0^2}{y^{10} - 1} \tag{91}
\end{equation}

Both in (89) and (90) the left hand side is independent of $u_0$, so the right hand is independent of it as well, and we find

\begin{equation}
m_{Vn/An}^2 \sim \frac{u_0^2}{R_{AdS}^4} \tag{92}
\end{equation}

\begin{equation}
g_{Vn/An} \sim \frac{u_0^2}{R_{AdS}^4} \tag{93}
\end{equation}

Plugging these into (42) we see that indeed the S-parameter is independent of $u_0$ in the limit $u_0 \gg 1$.

As was shown in the previous section for the Sakai Sugimoto model, we still need to determine the compactification scale of the system $M_\Lambda$. As before taking the technipion decay constant to equal the electro-weak scale, we find using the numerical integration

\begin{equation}
(246\text{GeV})^2 = \Pi_\Lambda(0) = F_\pi^2 = -\kappa_{nc} R_{AdS}^{-4} u_0^2 \gamma^{-1/2} \partial_u \psi_0^0(u, 0)|_{u=\infty} = 0.22 \kappa_{nc} M_\Lambda^2 \tag{94}
\end{equation}

and the corresponding mass scale is

\begin{equation}
M_\Lambda^2 = \frac{(246\text{GeV})^2}{0.0022 N_{TC}} \tag{95}
\end{equation}

For $N_{TC} = 4$ the scale is found to be 2.4TeV. Using this scale combined with the eigenvalues of (25) yields the following masses for the first two resonance:

\begin{equation}
m_{\rho T} = 1.79\text{TeV} \quad ; \quad m_{a_1 T} = 2.98\text{TeV} \tag{96}
\end{equation}
7 The KMMW model with D6 and anti-D6 flavor branes

As was emphasized in the last two sections, to have a chiral flavor symmetry of the form $U_L(N_{TF}) \times U_R(N_{TF})$ one has to place a set of $N_{TF}$ probe branes and anti-branes in such a way that the strings that stretch between them and between the original technicolor branes that constitute the background cannot have a non-trivial length. That required $D_8$ and $\bar{D}_8$ branes in the critical model and $D_4$ and anti-$D_4$ in the non-critical model. However, to play the role of technicolor one may use a non-chiral setup where a symmetry of two sets of Dirac fermions of the form $U_1(N_{TF}) \times U_2(N_{TF})$ is spontaneously broken to a diagonal symmetry $U_D(N_{TF})$. The dual of such a field theory can be realized by placing a stack of $D_6$ branes and $\bar{D}_6$ branes into Witten’s model [5]. The construction of the $D_4/D_6-\bar{D}_6$ system is identical to that of the Sakai Sugimoto model but with $D_6-\bar{D}_6$ probe branes instead of the $D_8-\bar{D}_8$. The profile of the probe branes is determined by solving the equations of motion for the three coordinates transverse to the branes. This was done by Kruczenski et al in [10]. The $D_6$ branes span the ordinary space-time coordinates, wrap an $S_2$ inside the $S_4$ and curve along the cigar spanned by $(u,x_4)$ coordinates. Obviously all the parameters of the background are those of [5] as was described in section (4). On the other hand, the induced metric is now

$$ds^2 = \left(\frac{u}{R_{D4}}\right)^{3/2}\left[-dt^2 + \delta_{ij}dx^idx^j\right] + R_{D4}^{3/2}u^{1/2}d\Omega_2^2 + \left(\left(\frac{u}{R_{D4}}\right)^{3/2}f(u)(\partial_u x_4)^2 + \left(\frac{R_{D4}}{u}\right)^{3/2}\frac{d}{du}\right)du^2$$

where we still sets $u_A = 1$. The curve of the $D_6-\bar{D}_6$ brane on the cigar spanned by $(u,x_4)$ is found via the DBI action to be

$$x_4(u) = u_0^{7/2}f(u_0)^{1/2} \int_{u_0}^{u} dx \frac{1}{x^{3/2}f(x)\sqrt{x^7 f(x) - u_0^7f(u_0)}}$$

In the terminology of section (3) this model is characterized by

$$\kappa_{nc} = -\frac{T_6(2\pi \alpha')^2V_2R_{D4}^3}{g_s} = \frac{N_{TC}}{(2\pi)^2} \approx .025N_{TC}$$

$$a(u) = \frac{\gamma}{u} \quad b(u) = \frac{u^2}{R_{D4}^3\gamma^{1/2}}$$

where

$$\gamma(u) = \frac{u^7}{u^7 f(u) - u_0^7 f(u_0)}$$
Integrating Numerically the equations of motion for the non-normalizable mode we find that for the antipodal configuration \( u_0 = u_\Lambda = 1 \)

\[
S = 4\pi \frac{d}{dq^2}(a^0_V(q^2) - a^0_A(q^2))|_{q^2=0} \approx 20.3\kappa_6 = 20.3 \times 0.025 N_{TC} = 0.5 N_{TC}
\]

(101)

For the general case \( u_0 > u_\Lambda = 1 \), we find a slow decrease of \( S \) towards the asymptotical value \( S \approx 18.49 \) so \( S \) virtually independent of \( u_0 \).

Now, we want to estimate the \( S \)-parameter using the sum over hadronic resonance given in (42) and see its agreement with (101). This requires the values of the decay constants of each of the vector and axial-vector mesons, and these are given as in (??) by:

\[
g_{Vn} = m^2_{Vn} a_{Vn} = -\kappa_6 R^{-3} u^2 \gamma^{-1/2} \partial_u \psi_{Vn}|_{u=\infty}
\]

(102)

\[
g_{An} = m^2_{An} a_{An} = -\kappa_6 R^{-3} u^2 \gamma^{-1/2} \partial_u \psi_{An}|_{u=\infty}
\]

(103)

We plugged this into (42) and summed up to \( n = 8 \) and found

\[
S_8 = 8.76\kappa_6 = 0.194 N_{TC}
\]

(104)

We see that as in the Sakai-Sugimoto model, the higher KK modes doesn’t decouple from the spectrum and \( S_n \) for some finite \( n \) doesn’t produce a good approximation for \( S \).

We repeat the scaling argument to determine qualitatively the dependance of the \( S \)-parameter on \( u_0 \) we. Changing to the dimensionless variable \( y = \frac{u}{u_0} \) in eq. (25) and (102), then in the limit \( u_0 >> 1 \) these become

\[
y \tilde{\gamma}^{-1/2} \partial_y (y^2 \tilde{\gamma}^{-1/2} \partial_y \tilde{\psi}_n(y)) = -\frac{m^2_{Vn} R^3}{u_0} \tilde{\psi}_n(y)
\]

(105)

\[
- \kappa_6 R^{-3} u^2 \gamma^{-1/2} \partial_u \psi_{Vn}|_{u=\infty} = \frac{g_{Vn}}{u_0}
\]

(106)

where we denoted

\[
\gamma \rightarrow \tilde{\gamma}(y) = \frac{y^7}{y^7 - 1}
\]

(107)

Both in (105) and (106) the left hand side is independent of \( u_0 \), so the right hand is independent of it as well, and we find

\[
m^2_{Vn/An} \sim \frac{u_0}{R^3}
\]

(108)
A brief look at (42) tells us that at the limit $u_0 \gg 1$, the S-parameter will exhibit independency of $u_0$.

As in the previous cases we determine the compactification scale of the model by equating the technipion decay constant to the electro-weak scale. Using numerical integration we find

$$\Pi_A(0) = F_\pi^2 = -\kappa_6(R)^{-3}u^2\gamma^{-1/2}\partial_u\psi^0(u)|_{u=\infty} = 0.47M_K^2\kappa_6 = (246\text{GeV})^2$$

For $N_{TC}$ this gives $M_{KK} = 1.1\text{TeV}$. Last we add that this mass scale set the masses of the first two resonance to be: $m_\rho = 0.7\text{TeV}$, $m_{a_1} = 1.16\text{TeV}$.

8 **D5 branes compactified on two circles with D7–D7 flavor branes**

Another interesting model in the context of HQCD is given by the near horizon limit of the non-extremal background of $N_c$ D5 branes. Now, adding $N_{TF}$ D7–D7 prob branes into this background we get open strings between the D5 to the D7 which are fundamentals of the $SU(N_c)$ gauge group in doublets of $SU(N_{TF})$. The fields in this background are given by

$$ds^2 = \frac{u}{R}(\eta_{\mu\nu}dx_\mu dx_\nu + dx_4^2 + f(u,u_\Lambda)dx_5^2) + \frac{R}{u} \frac{du^2}{f(u,u_\Lambda)} + Rud\Omega_3^2$$

where

$$f(u,u_\Lambda) = \left(1 - \frac{u_\Lambda^2}{u^2}\right) ; \quad R^2 = g_sN_c\alpha'$$

and the dilaton and 3 form field strength are given by

$$\exp(\phi) = g_s\frac{u}{R} ; \quad F_3 = \frac{2R^2}{g_s}\Omega_3$$

In this model $x_4$ and $x_5$ are compact

$$x_4 = x_4 + 2\pi R_{x_4} ; \quad x_5 = x_5 + 2\pi R_{x_5}$$

where in order to avoid conical singularity we must set $R_{x_5} = R$. We choose the D7–D7 prob branes to be space filling and flat in the $M_4$ and $S_3$ directions and
curves on the \((u, x_4, x_5)\) space. We choose to parameterize the curve by the \(u\) coordinate \((x_4(u), x_5(u), u)\) where the functions \(x_4(u)\) and \(x_5(u)\) will be determined by the minimization of the DBI action

\[
S_{D7} = \frac{T_7 V_5 V_4}{g_s} \int du u^3 \sqrt{(\partial_u x_4)^2 + f(u, u_\Lambda) (\partial_u x_5)^2 + \frac{R^2}{u^2 f(u, u_\Lambda)}}
\]

(115)

and we find (from here on we will set \(u_\Lambda = 1\))

\[
x_4(u) = P_4 R \int_{u_0}^u \frac{du'}{u'^2 f(u') \left( u'^6 - P_4^2 - \frac{P_5^2}{f(u')} \right)}
\]

(116)

\[
x_5(u) = P_5 R \int_{u_0}^u \frac{du'}{u'^2 f(u')^3 \left( u'^6 - P_4^2 - \frac{P_5^2}{f(u')} \right)}
\]

(117)

For detailed description of the solutions as a function of the integration constants \(P_4\) and \(P_5\) see [?]. The induced metric is therefore

\[
ds^2 = \left( \frac{u}{R} \right) \left[ \eta_{\mu\nu} dx^\mu dx^\nu + \left( (\partial_u x_4(u))^2 + f(u, u_\Lambda) (\partial_u x_5(u))^2 + \frac{R^2}{u^2 f(u, u_\Lambda)} \right) du^2 + R^2 d\Omega_3^2 \right]
\]

(118)

where we defined

\[
\gamma(u) \equiv \frac{u^6}{f(u) \left( u^6 - P_4^2 - \frac{P_5^2}{f(u)} \right)}
\]

(119)

The DBI action for the gauge fields on the \(D7\) prob branes reads

\[
S_{F2} = -\frac{R^3 (2\pi \alpha')^2 T_7 \Omega_3}{4 g_s} Tr \int d^4 u \left( \gamma^{1/2}(u) F_{\mu\nu} F^{\mu\nu} + \frac{2u^2}{R^2 \gamma^{1/2}(u)} F_{\mu u} F^{\mu u} \right)
\]

(120)

Using mode decomposition as in [24], the equation of motion for the \(\psi_n\) are

\[
\gamma^{-1/2} \partial_u (u^2 \gamma^{-1/2} \partial_u \psi_n(u)) = -m_n^2 R^2 \psi_n(u)
\]

(121)

and for the non-normalizable part it is

\[
\gamma^{-1/2} \partial_u (u^2 \gamma^{-1/2} \partial_u \psi^0(u, q^2)) = -q^2 R^2 \psi^0(u, q^2)
\]

(122)
For the antipodal case \( P_4 = P_5 = 0, u_0 = 1 \), (121) and (122) will simplify to

\[
f^{1/2} \partial_u (u^2 f^{1/2} \partial_u \psi_n(u)) = -m_n^2 R^2 \psi_n(u) \tag{123}
\]

and

\[
f^{1/2} \partial_u (u^2 f^{1/2} \partial_u \psi_n(u, q^2)) = -q^2 R^2 \psi_n(u, q^2) \tag{124}
\]

After the change of variable \( u^2 = 1 + z^2 \), we find

\[
\partial_z ((1 + z^2) \partial_z \psi_n(z)) = -m_n^2 R^2 \psi_n(z) \tag{125}
\]

and

\[
\partial_z ((1 + z^2) \partial_z \psi^0(q^2, z)) = -q^2 R^2 \psi^0(q^2, z) \tag{126}
\]

One can transform (125) into a standard Schrödinger form via the transformation

\[
z = \sinh(x) \quad ; \quad \psi_n(x) = \frac{1}{\sqrt{\cosh(x)}} \Psi_n(x) \tag{127}
\]

and find

\[
 \left( \partial^2_x - \frac{1}{4} \left( 1 + \frac{1}{\cosh^2(x)} \right) \right) \psi_n = -m_n^2 R^2 \psi_n \tag{128}
\]

This eigenvalue problem has only two normalizable solutions and so the sum in (42) runs only on these two modes.

Substituting (24) into (120) we get 4d YM action for the gauge fields with the kinetic terms canonically normalized provided the \( SU(N) \) generator obey \( Tr[T^a T^b] = \frac{1}{2} \delta^{ab} \) and the \( \psi_n \) are normalized as

\[
\frac{R^3 (2 \pi \alpha')^2 T_7 \Omega_3}{g_s} \int du \psi_{Vn} \psi_{Vm} \gamma^{1/2} = \delta_{nm} \tag{129}
\]

\[
\frac{2 R^3 (\pi \alpha')^2 T_7 \Omega_3}{g_s} \int du \psi_{An} \psi_{Am} \gamma^{1/2} = \delta_{nm} \tag{130}
\]

According to our prescription in section (3) the boundary terms , (29), (33) will be given by

\[
a_{Vn} = -\kappa_7 (m_n^2 R^2)^{-1} u^2 \gamma^{-1/2} \partial_u \psi_{Vn}\big|_{u=\infty} \tag{131}
\]

\[
a_{An} = -\kappa_7 (m_n^2 R^2)^{-1} u^2 \gamma^{-1/2} \partial_u \psi_{An}\big|_{u=\infty} \tag{132}
\]
\[ a_{V0} = -\kappa R^{-2} u^2 \gamma^{-1/2} \partial_u \psi^0_V(u, q^2) \big|_{u=\infty} \tag{133} \]
\[ a_{A0} = -\kappa R^{-2} u^2 \gamma^{-1/2} \partial_u \psi^0_A(u, q^2) \big|_{u=\infty} \tag{134} \]

Where we defined
\[ \kappa = \frac{u \Lambda R^3 (2\pi \alpha')^2 \kappa \Omega_3}{g_s} \tag{135} \]

The correlators of the vector and axial-vector currents are given by the AdS/CFT prescription \([40]\), and we find
\[ \Pi_V(q^2) \equiv \langle J^\mu_V(q^2) J^\nu_V(0) \rangle_{F.T} = -a_{V0}(q^2) \tag{136} \]
and
\[ \Pi_A(q^2) \equiv \langle J^\mu_A(q^2) J^\nu_A(0) \rangle_{F.T} = -a_{A0}(q^2) \tag{137} \]

\[ S = -4\pi \frac{d}{dq^2} (\Pi_V - \Pi_A)|_{q^2=0} = -4\pi \frac{d}{dq^2} (a_{V0}^0(q^2) - a_{A0}^0(q^2))|_{q^2=0} \tag{138} \]

For the antipodal configuration \((u_0 = u_{\Lambda} = 1)\) \([133], [134]\) becomes

\[ a_0 = -\kappa R^{-2} u^2 f^{1/2} \partial_u \psi^0(u, q^2) \big|_{u=\infty} = -\kappa (R)^{-2} \frac{u^3}{z} f^{1/2} \partial_z \psi^0(u, q^2) \big|_{z=\infty} \tag{139} \]

using \(uf^{1/2} = z\) we find
\[ a_0 = -\kappa R^{-2} (1 + z^2) \partial_z \psi^0(u, q^2) \big|_{z=\infty} \tag{140} \]

The asymptotic behavior of \(\psi^0_V(u, q^2)\) could be read from \([126]\) by expanding it in powers of \(z^{-1}\). Keeping only the leading order term \([126]\) becomes
\[ \partial_z (z^2 \partial_z \psi) = -q^2 \psi(q^2, z) \tag{141} \]

This has the form of an Euler equation and can be solved using \(\psi(q^2, z) = z^{\alpha_q}\) which leads to an equation for \(\alpha_q\)
\[ \alpha_q (\alpha_q - 1) + 2\alpha_q + q^2 = \alpha_q^2 + \alpha_q + q^2 = 0 \tag{142} \]

with the roots
\[ \alpha_q = \frac{-1 \pm \sqrt{1 - 4q^2}}{2} = \frac{-1}{2} \pm \frac{1}{2} \mp q^2 \tag{143} \]

So we have two asymptotic behavior \(\alpha_q^- = -1 + q^2\) and \(\alpha_q^+ = -q^2\). One correspond to the even mode and one to the odd mode. Plugging these solution into \([138]\) would lead to a diverging \(S\)-parameter!
9  The conifold model with $D7-\bar{D}7$ flavor branes

So far we have discussed the $S$ parameter of holographic technicolor models that are based on gravity backgrounds with a cigar like structure of the sub-manifold that includes a coordinate compactified on an $S^1$ circle and the radial direction. This structure of the background ensures the confining nature of the dual gauge theory and the U shape solutions for the probe brane profile implies the spontaneous breaking of its flavor chiral symmetry. Recently, another type of a holographic model that admit these two features and which is based on the conifold geometry was proposed in [12] and [13]. In this section we show that this model also fits the general framework discussed in section 3 and we determine the $S$ parameter of the holographic technicolor scenario based on this model.

In fact we can discuss two such models. One based on the conifold geometry which is a conformal model that does not admit confinement [12] and a one which relates to the deformed conifold [13] which is a confining model. To simplify the analysis we discuss here the former but a similar type of calculation can be done also to the latter. Thus we consider here the conifold background. The flavor probe brane is taken to be a $D7$ and $\bar{D}7$ anti brane. It spans the space-time coordinates $x_\mu$, the radial direction $u$ and the three-sphere parameterized by the forms $f_i$ (or alternatively $w_i$). The transversal space is given by the two-sphere coordinates $\theta$ and $\phi$. The classical profile depend only on the radial coordinate.

The 10d metric is:

$$ds^2_{(10)} = \frac{u^2}{R_{AdS}^2} dx_\mu dx^\mu + \frac{R_{AdS}^2}{u^2} ds^2_{(6)}$$

with the 6d metric given by

$$ds^2_{(6)} = dr^2 + \frac{r^2}{3} \left( \frac{1}{4} (f_1^2 + f_2^2) + \frac{1}{3} f_3^2 + (d\theta - \frac{1}{2} f_2) d\phi + \sin(\theta) d\phi - \frac{1}{2} f_1^2 \right)$$

and the $AdS_5$ radius is $R_{AdS}^4 = \frac{\pi g_s N_{TC}}{4}$. Because the background has no fluxes except for the $C_4$ form the Chern-Simons terms do not contribute and the action consists only of the DBI part

$$S_{DBI} \propto \int du u^3 \left( 1 + \frac{u^2}{6} \left( \theta_a^2 + \sin^2 \theta \phi_u^2 \right) \right)^{1/2}.$$  

Here the subscript $u$ stands for the derivatives with respect to $u$. Setting $\theta = \pi/2$ we easily find the solution of the equation of motion

$$\cos \left( \frac{4}{\sqrt{6}} \phi(u) \right) = \left( \frac{u_0}{u} \right)^4.$$  

There are two branches of solutions for $\phi$ in (147) with $\phi \in [-\pi/2, 0]$ or $\phi \in [0, \pi/2]$. For $u_0 = 0$ we have two fixed ($u$-independent) solutions at $\phi_- = -\frac{\sqrt{3}}{8} \pi$ and $\phi_+ = \frac{\sqrt{3}}{8} \pi$.
The induced 8d metric in this case is that of $AdS_5 \times S^3$ as one can verify by plugging $d\phi = d\theta = 0$ into (145). For non-zero $u_0$ the radial coordinate extends from $u = u_0$ (for $\phi = 0$) to infinity (where $\phi(u)$ approaches one of the asymptotic values $\phi_{\pm}$). The induced metric has no $AdS_5 \times S^3$ structure anymore. Notice that unlike the case of the Sakai Sugimoto model, here the $D7$ probe branes do not reside at the antipodal points on the $(\theta, \phi)$ two-sphere. This is due to the the conical singularity at the tip, so the $S^2$ does not shrink smoothly.

It is convenient to define a new dimensionless radial coordinate

$$z = \frac{u}{R_{AdS}} \sqrt{(1 - \frac{u_0^8}{u^8})}$$ (148)

so that the $D7$ probe brane stretches along positive $z$ and the anti-brane along negative $z$.

In terms of these the gauge fields action is given by

$$S_{KW} = \kappa_7 Tr \int d^4xdz \left[ \frac{F_{\mu\nu}^2}{\sqrt{z^2 + \frac{u_0}{R_{AdS}}}} \right] + 16 \left( z^2 + \left( \frac{u_0}{R_{AdS}} \right)^8 \right)^{3/2} F_{\mu z}^2$$ (149)

This form of the action translate into the following parameters in the framework for computing the $S$ parameter are

$$\kappa_7 = 0.0011 N_{TC}$$

$$\hat{a}(z) = \frac{1}{\sqrt{z^2 + u_0^8}} \quad \hat{b}(z) = 16 \left( z^2 + \left( \frac{u_0}{R_{AdS}} \right)^8 \right)^{3/4}$$ (150)

Repeating the procedure of determining the $S$ parameter using (11) we find

$$S = 0.043 N_{TC}$$ (151)

and the result using the sum-rule (12) is

$$S_8 = 0.036 N_{TC}$$ (152)

For comparison we substitute $N_{TC} = 4$ to yield $S = 0.17$ and $S_8 = 0.114$. Equating as before the technipion decay constant to the electroweak scale we find that $M_\Lambda$ is given by

$$M_\Lambda^2 = \frac{(246 \text{GeV})^2}{0.202 N_{TC}}$$ (153)

so that for $N_{TC} = 4$ we get $M_\Lambda = 1.5 \text{TeV}$ which gives $m_\rho = 3 \text{TeV}$ , $m_{a_1} = 5 \text{TeV}$.

10 Summary

In this paper we have examined a variety of technicolor models through their holographic duals. We have focused mainly on the S-parameter of these models. For that purpose we presented the method used in [3] to deduce the holographic S-parameter and showed how to apply the technique to general (suitable) background and then applied it on several models. Generically Technicolor models admit a confinement behavior and spontaneous flavor chiral symmetry breaking. Indeed some of the models we have chosen, the Sakai Sugimoto model, the non-critical model and the model based on $D5$ branes admit both these properties in their low energy regime. However, we have chosen also other type of models. The uncompactified Sakai Sugimoto model is dual to a NJL like model. It does not admit confinement but does undergo a spontaneous flavor chiral symmetry breaking. The confifold model is also non-confining. In fact prior to adding the flavor branes it is invariant under conformal symmetry which is spontaneously broken due to the addition of the flavor branes. The KMMW model with $D6$ branes is confining and it has a symmetry breaking of the form $U(N_{TF}) \times U(N_{TF}) \rightarrow U_V(N_{TF})$. However, it is not a symmetry of chiral fermions but rather a symmetry of Dirac fermions. From the point of view of the S-parameters there is not much difference between the models that admits both confinement and spontaneous flavor chiral symmetry breaking to the other models.

The direct estimation of the Peskin-Takeuchi S-parameter for a strongly interacting sector is still a grave problem in technicolor model-building. But as was shown in [3] for the Sakai-Sugimoto model, and also in the present paper a reliable estimate for the S-parameter is with in reach if the field theory has a gravity dual. Strictly speaking the latter applies only for large $N_{TC}$ and large $\lambda_{TC}$.

The results of the S-parameter and the low lying technivector mesons is summarized in table 1.

In general the S-parameter is a function of all the free parameters of the theory $N_{TC}, \lambda_{TC}, N_{TF}$ and $u_0$ or instead the “string endpoint” masses defined in (43). As for the dependence on $N_{TC}$ and $\lambda_{TC}$ there is a striking difference between the Sakai-Sugimoto model both the compactified and the uncompactified and the rest of the models. Whereas in the former models $S$ depends linearly on the product of $N_{TC}\lambda_{TC}$, in the latter models it does not depend on $\lambda_{TC}$ but rather it is linear only in $N_{TC}$. The dependence of the S-parameter on $u_0$ in some of the models is drawn in figure 2.

We can see from this figure that while the S-parameter in Sakai-Sugimoto model (and also its uncompactified cousin) grows linearly with $u_0$, the $D4-D6$ and $AdS_6+D4$ models exhibit minor dependence on this parameter. As explained around (43) the $u_0$ parameter is related to the string endpoint mass which is given roughly by $\frac{M_m - T_{st} L}{2}$ where $M_m$ is the mass of the corresponding meson, $T_{st}$ is the string tension and $L$ is the length of
The S-parameter of the D4-D8, D4-D6 and the non-critical models versus $U_0$.

Figure 2: S-parameter of the $AdS_6 + D4$ non-critical model, $D4 - D8$, and $D4 - D6$ models vs. $u_0$ ($u_Λ = 1$).

Table 1: The S-parameter of the six models, $N_{TF} = 2$, $S$ is given by the AdS/CFT dictionary, $S_8$ is the sum over the first eight modes in (42).

the stringy meson. This mass parameter has nothing to do with the current algebra or “QCD” mass and hence one cannot compare it to the dependence on the mass found in [1] at the weak coupling regime.

The dependence on $N_{TF}$ is more tricky. If one naively embed the $U(2) \in U(N_{TF})$ in such a way that the generator of $SU(2)$ for instance $T_3$ is just one and -minus one in the upper terms along the diagonal, then there is no dependence of the $S$ parameter on $N_{TF}$ since it relates to the electroweak currents that are affected only by the upper $2 \times 2$ block of the $N_{TF} \times N_{TF}$ matrices. However, if we generalize the models discussed in the paper with only a single factor of $SU(N_{TF} = 2)$, to a set of $N_{TF}$ of such group factors, this should yield an $S$ parameter which is $N_{TF}$ times bigger than the one of a single group factor. The holographic realization of such a scenario is by taking $\frac{N_{TF}}{2}$ pairs of U shape flavor probe brane and distribute them along the radial direction, namely assign to each of them a different $u_0$. In the non-critical, KMMW and KW + D7 models the $S$-parameter barely depends on $u_0$ and hence a summation over all the pairs of U-shape flavor branes is definitely justified. However for the Skai Sugimoto model and his uncompactified cousin, the $S$-parameter depends linearly on $u_0$ and thus a naive summation is incorrect. One can of course introduce very small differences in the values of the $u_0$ associated with each pair and in this way the summation result will be a reasonable approximation.

We demonstrate these results for the $AdS_6 + D4$ non-critical model and the KMMW
model. For the anti-podal configuration \( S \) is given by

\[
S = 10.3 \kappa_{nc} = 10.3 \sqrt{\frac{53 N_{TF}N_{TC}}{32\pi^3}} = 0.048N_{TF}N_{TC}
\]  

(154)

and in the \( D4 - D6 \) system it is

\[
S = 20.3 \kappa_6 = 20.3 \frac{N_{TF}N_{TC}}{2(2\pi)^2} = .25N_{TF}N_{TC}
\]

(155)

Of course holography is not the only way to estimate the S-parameter, in \( [1] \) a few phenomenological formula where suggested in order to estimate the S-parameter of technicolor models with QCD like dynamics. The starting point of their formulas is to use eq. \( (42) \) with the masses and decay constants of the techni-hadrons given by assuming the large-\( N \) rescaling relations between these to their QCD counterparts. They found by summing over the first two hadronic resonance \( \rho_{TC} \) and \( a_{1Tc} \), that for a model with \( SU(N_{TC}) \) technicolor gauge group and \( N_{TF} \) \( SU(2) \) doublets \( S \) is given by

\[
S_2 \approx 0.247 \frac{N_{TF}N_{TC}}{3}
\]

(156)

While our holographic summation over the first two resonance gave

\[
S_{2,AdS_6} \approx 0.213 \frac{N_{TF}N_{TC}}{3}
\]

(157)

Comparing these two estimates reveals a remarkable agreement between these two very different machineries!

We can continue and compare the estimated mesons masses according to the large-\( N \) scaling relations

\[
m^2_{\rho_T} \approx \frac{6}{N_{TC}N_{TF}} \frac{F^2_{\pi}m^2_{\rho}}{f^2_{\pi}} \quad m^2_{a_{1T}} \approx \frac{6}{N_{TC}N_{TF}} \frac{F^2_{\pi}m^2_{a_{1}}}{f^2_{\pi}}
\]

(158)

using the data

\[
m_{\rho} \approx 775\text{MeV} \quad m_{a_{1}} \approx 1230\text{MeV} \quad F^2_{\pi} \approx (246\text{GeV})^2 \quad f^2_{\pi} \approx (92\text{GeV})^2
\]

(159)

we find for \( N_{TC} = 4 \) and \( N_{TF} = 2 \)

\[
m_{\rho_T} \approx 1.79\text{TeV} \quad m_{a_{1T}} \approx 2.8\text{TeV}
\]

(160)

By holography we found in \( [96] \) (using \( [94] \) to set the Kaluza-Klein scale to \( M_A = 2.4\text{TeV} \) by which we measure all quantities in the theory)

\[
m_{\rho_T} \approx 0.74M_A = 1.78\text{TeV} \quad m_{a_{1T}} \approx 1.23M_A = 2.98\text{TeV}
\]

(161)

Again we find an agreement within a few percent between the two.
Acknowledgements

It is a pleasure to thank Ofer Aharony for very useful conversations and for his comments on the manuscript. We are also grateful to Stanislav Kuperstein for fruitful discussions. This work was supported in part by a centre of excellence supported by the Israel Science Foundation (grant number 1468/06), by a grant (DIP H52) of the German Israel Project Cooperation, by a BSF grant, by the European Network MRTN-CT-2004-512194 and by European Union Excellence Grant MEXT-CT-2003-509661.
