Prevalence of Third Molar Agenesis in Patients—A Panoramic Retrospective Study

Vivek Padmanabhan1, Omar Khaled AR Abo Mostafa2, Lama M Kamel Rahhal3

ABSTRACT

Background/purpose: The most common developmental dental problem is that of agenesis. It is seen to affect around about 25% of the population. The aim of this study is to determine the prevalence of agenesis of third molars in patients visiting a dental college in the UAE.

Materials and methods: Orthopantomograms (OPGs) of 945 dental patients aged 6–30 years were evaluated for bilateral agenesis or congenitally missing teeth. Bilateral agenesis was considered and unilateral missing teeth were excluded from the study. Descriptive statistics were used to describe the percentages and frequencies were calculated using Chi-square test and the level of significance was considered if the p value was <0.05.

Results: Eighty-five of the 945 OPGs showed bilateral agenesis. The prevalence of bilateral agenesis or congenitally missing third molars within the selected 85 OPGs was at 31.76%.

Conclusions: The prevalence rate of bilateral agenesis or congenitally missing permanent third molars is high at 31.76%.

Keywords: Agenesis, Orthopantomograms, Third molars.

Journal of Contemporary Dentistry (2020): 10.5005/jp-journals-10031-1301

INTRODUCTION

Teeth which have not erupted at their usual times of eruption into the oral cavity are known by the term “agenesis.” It is one of the most common dental anomalies found in human beings. Whenever there is a complete absence of teeth, it is referred to as “anodontia.” When the number of missing teeth is six or more, then it is referred to as “oligodontia.”1,2 Hypodontia is a term used to refer to a condition when there are less than six teeth found missing.2

The tooth with the highest prevalence rate of agenesis is usually the third molar and is also referred to as “vestigial” at times.3,4 Ever since the evolution of human beings has occurred, there have been dramatic cultural and biological changes that have taken place in the human race, and these changes have also been reflected in the diet of human beings.3 The diet of humans is now more refined when compared to our ancestors, and this has also been suggested as a reason for decreasing dependency on the third molars and also reduced jaw size, resulting in an increasing prevalence of agenesis of third molars as evolution has happened.3,4

One of the characteristic features of third molars is the variability that it exhibits in its formation and odontogenesis and by its varying rates of being present or absent within the oral cavity.3 The different stages of odontogenesis of third molars inclusive of development, calcification, and eruption show a huge variation. At times, the development of the third molars can be initiated at the age of 5 years or maybe toward the early 7th year of life. The calcification of the third molars can begin as early as at the age of 7 years or can be delayed until the age of 16–17 years in some individuals.3,4 The etiology of agenesis could be attributed to environmental factors, genetic polymorphisms, systemic diseases, dietary habits, and masticatory function.3,4 The genetic etiology is usually attributed to the mutation of some genes (PAX9 and MSX1) in addition to some other etiological reasons in the prenatal and postnatal periods.3,4 Studies which compared the gender predilection suggested that the prevalence of agenesis was more in women than men.3,4 Racial comparisons revealed that there is a lesser rate of prevalence in the black race when compared to the whites and that Asians showed an increased prevalence of agenesis.10 There have been studies which have shown a prevalence of 12.7% in the British population.11 Another study among the Chilean population showed a prevalence rate of 24.75%12 and a high prevalence rate of 41% was seen in the Korean population.13 These variations can be attributed to factors like sample size, the population included, race investigated, and also not to forget genetic mutations which can result in agenesis as a result of evolution also.

The present study is designed to understand the prevalence of bilateral agenesis of the third molars among a population of patients visiting a dental college in the UAE. The study is also intended to understand the gender and arch predilection of bilateral agenesis of the third molars.

MATERIALS AND METHODS

This was a retrospective, observational study conducted after approval from the Research and Ethics Committee at RAK College of Dental Sciences (RAKCODS), RAK Medical and Health Sciences University, Ras Al Khaimah, United Arab Emirates.

University (RAKMHSU), RAK, UAE. The objective of this study is to understand the prevalence of bilateral agenesis of the third molars. The study is also intended to evaluate the gender and arch predilection of bilateral agenesis of the third molars. The age-group of patients for whom the orthopantomograms (OPGs) were selected was between 6 years and 30 years of age. Orthopantomograms which showed bilateral agenesis of the third molars were included.

Since a clinical examination of these patients was not possible, only those OPGs which showed bilateral absence were considered to be true agenesis and were included in the present study.

Nine hundred forty-five OPGs at the oral radiology center of the university were used out of the total 18,500 OPGs available. These 945 OPGs were selected based upon the age-group, clarity of the OPG, presence of details in the OPG, and E-file of patients on the hospital information management system (HIMS). Patients with syndromes or other special needs patients as per the E-file records on HIMS were excluded from the study and also edentulous patients were not included. Also, patients who had periapical X-rays on their files which showed possible extraction of these (third molars, mandibular second premolars, and maxillary lateral incisors) teeth were excluded from the study. Once these 945 OPGs were selected, then a second level of inclusion and exclusion criteria in terms of evaluating for bilateral agenesis of the third molars was used to understand the prevalence of bilateral agenesis.

**Statistical Analysis**

Data observed in this study were described using descriptive statistical analysis. To evaluate the frequency of agenesis between sexes (males/females) and between the maxillary and mandibular arches where applicable Chi-square statistical test was applied, the level of significance was set at $p < 0.05$.

**Results**

A total of 945 OPGs were initially included in the study of the 18,500 OPGs which were available for review in the dental radiology center of the university. These OPGs were initially evaluated based upon the criteria like age-group. Then, these 945 OPGs were categorized based upon the presence of bilateral agenesis.

Eighty-five OPGs of the 945 OPGs revealed bilateral agenesis of teeth; of the 85 OPGs which revealed bilateral agenesis, 31.76% showed bilateral agenesis or congenitally missing third molars. Hence, the prevalence of bilateral agenesis of the third molars or congenitally missing third molars is 31.76% (27 OPGs showed bilateral agenesis of the third molar) (Fig. 1). The 27 OPGs which showed bilateral agenesis comprised 15 males and 12 females.

The prevalence of bilateral agenesis or congenitally missing teeth was seen more in males (55.55%) than females (44.44%) (Table 1); within these 27 OPGs, the results were, however, not statistically significant ($X^2 = 0.84, p = 0.30$).

The prevalence of bilateral agenesis or congenitally missing teeth was more in the mandibular arch (51.85%) than the maxillary arch (48.14%) (Table 2); within these 27 OPGs, these results were also not statistically significant ($X^2 = 1.30, p = 0.26$).

**Discussion**

The most common dental anomaly in humans is tooth agenesis and this agenesis is at times associated with other anomalies, structural malformations, delayed eruption, crowding, and juxtaposition. Agenesis of teeth can affect both primary and permanent dentition.

**Table 1: Prevalence of bilateral agenesis of third molars or congenitally absent third molars between males and females**

| Total | Male | Female | $X^2$ (Chi-square) | Sig p value |
|-------|------|--------|-------------------|-------------|
| 27    | 15   | 12     | 0.84              | 0.30        |
| 100%  | 55.55%| 44.44% |                   |             |

**Table 2: Prevalence of bilateral agenesis of third molars or congenitally missing third molars between maxillary and mandibular arches**

| Total | Maxillary arch | Mandibular arch | $X^2$ (Chi-square) | Sig p value |
|-------|---------------|----------------|-------------------|-------------|
| 27    | 13            | 14             | 1.30              | 0.26        |
| 100%  | 48.14%        | 51.85%         |                   |             |

**Fig. 1:** Prevalence (%) of bilateral agenesis of the third molar or congenitally absent third molars

**Bilateral Agenesis or Congenital Absence of Third Molars**

In the present study, it was seen that the prevalence rate of bilateral agenesis or congenitally missing third molars is at 31.76%. The high prevalence of third molar agenesis seen in the present study can be attributed to many factors such as genetic predisposition, nutritional status, and socioeconomic status. The study also highlights the importance of early detection and intervention to prevent complications associated with bilateral agenesis.
be due to the reduced number of OPGs which were included in the present study; however, yet the percentage remains high. There are studies which have reported high percentages, ranging from 24.75 to 41%. Genetics seems to play an important role in these high prevalence rates usually found in studies. Bone morphogenetic protein-4, produced early in dental epithelial development, regulates mesenchymal tooth-specific gene expression, including that of the MSX1 gene. A missense mutation in the MSX1 gene at chromosome 4p16.1 appears to be responsible for the third molar agenesis. The synergistic effects of both the genetic influence and the corresponding growth factors are possibly associated with agenesis of the third molars. Further, it has been suggested that third molar agenesis is also associated with decreased maxillary and mandibular jaw size as a result of continuous human evolution.

Gender Predilection

The prevalence of bilateral agenesis or congenitally missing teeth was seen more in males (55.55%) than females (44.44%) (Table 1). The results of the present study are similar to those of studies done in Iran, Australia, and Finland, which also showed higher incidence rates in males when compared to females. However, there are other studies which usually have shown increased incidence rates in females compared to males. It has been shown in studies that the prevalence of hypodontia is usually higher in females. Though there are not many plausible reasons that have been found in the literature regarding this finding of increased prevalence in either gender, there was a suggestion in one of the studies by Graber where it is suggested that genetics plays an important role in intersexual differences, though not much of an explanation was given.

Arch Predilection

The prevalence of bilateral agenesis or congenitally missing third molars was more in the mandibular arch (51.85%) than the maxillary arch (48.14%) (Table 2). A similar prevalence rate was found in a Swedish study done by Backman et al. However, there are other studies which have shown a higher rate of prevalence of congenital absence of teeth in the maxillary arch when compared to the mandibular arch. The reason provided for a higher prevalence in the maxilla was suggested to be due to the presence of different innervations. In the present study, though there was a higher prevalence in the mandibular arch, it was not statistically significant and we have no plausible reasons to suggest this as a cause for this finding.

At the end of this study, the authors agreed that there should be more studies done to understand the influence genetics can have on the agenesis of teeth and what evolution of human beings means to the agenesis of the third molars. The authors believed that if there is more evolution of the human race, then there can be a time when the third molars may cease to exist.

**Conclusion**

In the present study, we found that

- The prevalence rate of bilateral agenesis or congenitally missing third molars is high.
- The bilateral agenesis or congenitally missing third molars was found to have a high prevalence in males when compared to females.
- The bilateral agenesis or congenitally missing third molars was found to be more common in the mandible than the maxilla.
