Spectral Profiles, a Novel Representation of Tandem Mass Spectra and Their Applications for \emph{de Novo} Peptide Sequencing and Identification*\textsuperscript{[S]}

Sangtae Kim, Nuno Bandeira, and Pavel A. Pevzner‡

Despite many efforts in the last decade, the progress in \emph{de novo} peptide sequencing has been slow with only 30–45% of all peptides correctly reconstructed. We argue that accurate \emph{full-length} peptide sequencing may be an unattainable goal for some spectra and demonstrate how to accurately sequence \emph{gapped} peptides instead. We further argue that gapped peptides are nearly as useful as full-length peptides for error-tolerant database searches. Gapped peptides occupy a niche between long but inaccurate full-length reconstructions and short but accurate peptide sequence tags. Our MS-Profile tool uses spectral profiles, a new representation of tandem mass spectra, to generate gapped peptides that are longer and more accurate than peptide sequence tags of length 3 traditionally used to speed up database searches in proteomics. In addition, spectral profiles also enable intuitive visualization of all high scoring \emph{de novo} reconstructions of tandem mass spectra. \textit{Molecular & Cellular Proteomics} 8: 1391–1400, 2009.

Recent advances in \emph{de novo} peptide sequencing have enabled tag-based peptide identification tools (e.g. Inspect (1) and Paragon (2)) that are orders of magnitude faster than traditional MS/MS database search approaches (e.g. Sequest (3) and Mascot (4)). However, reliable full-length \emph{de novo} peptide sequencing remains an elusive goal, and even the most accurate \emph{de novo} tools correctly reconstruct only 30–45% of peptides (5). We argue that accurate full-length \emph{de novo} peptide sequencing may be an unattainable goal for many spectra because they do not provide enough information to disambiguate between correct and incorrect reconstructions. Spectra often have variable local quality (along the peptide length) making some regions not amenable to \emph{de novo} sequencing. For example, spectra of peptides DGEEAAENTDAQK and DSSAAENTDAQK are very similar (supplemental Fig. S1) making it nearly impossible to reliably reconstruct these peptides \emph{de novo} (the combined mass of Gly and Glu is close to the combined mass of Ser and Val). In such cases, it makes more sense to reconstruct a \emph{gapped} peptide D[186]AENTDAQK rather than a contiguous peptide (186 Da refers to the rounded combined mass of Gly and Glu or Ser and Val). Although gapped peptides are less informative than full-length peptides, we argue that there is little difference between these two representations. Indeed in most applications, \emph{de novo} peptide sequencing is not the final goal in analyzing a spectrum but rather a prelude to error-tolerant database searches and other applications like metaproteomics (6–9). We argue that \emph{long} gapped peptides are nearly as good for such applications as full-length \emph{de novo} reconstructions. For example, the gapped peptide D[186]AENTDAQK has 9 continuous amino acids and thus, for all practical applications, is at least as useful as any peptide of length 9 (or length 11 if one counts Asp and [186] as separate “letters”). Because most mass spectrometrists view peptides of length 9 as useful as peptides of length 12, generating sufficiently long gapped peptides is nearly as useful as generating full-length reconstructions (the full length of D[186]AENTDAQK is 12).

In this study we introduce the notion of a \textit{spectral profile} (Fig. 1) that enables accurate \emph{de novo} sequencing of gapped peptides and reveals the variable spectral quality along the peptide length. For example, for peptides of length 11–12, our MS-Profile tool correctly reconstructs 65% of gapped peptides as compared with 46, 28, and 26% correct reconstructions of full or truncated full-length peptides by PepNovo+ (5, 10), MS-Dictionary (11), and PEAKS (12). Gapped peptides occupy a niche between peptide sequence tags (that in most applications are limited to tags of length 3) and full-length reconstructions: they are nearly as accurate as short tags and, at the same time, typically have a unique match in the protein database. For example, for peptides of length 12, the average length of gapped reconstructions is 8.9, typically resulting in a single hit even when searching against the largest databases used in proteomics today.\textsuperscript{1}

\textsuperscript{1} We define the length of the gapped peptide as the number of masses and amino acids describing the peptide. For example, the length of the gapped peptide [186]DK[246]FK is 6, whereas the length of a 3-aa long peptide sequence tag [307]GTP[421] is 5.
A spectral profile is a novel representation of tandem mass spectra with "intensities" of all masses varying from 0 to 1. Every peptide of length \( n \) defines \( n \) prefix masses representing masses of the first \( i \) amino acids (for \( 1 \leq i \leq n \)). The spectral profile at mass \( x \) is the proportion of peptides with prefix mass \( x \) among all high scoring interpretations of the spectrum. Thus, the spectral profile compactly represents information about all high scoring de novo reconstructions (spectral dictionaries) even if there are billions of such reconstructions (see Ref. 11). Spectral profiles are conceptually similar to the motif profiles (13) (supplemental Fig. S2) that are used in various areas of bioinformatics (e.g. in regulatory genomics). Whereas motif profiles in regulatory genomics compactly represent all known binding sites of a transcription factor, a spectral profile compactly represents all high scoring de novo reconstructions of an MS/MS spectrum. However, whereas motif profiles represent the center of gravity of known motifs, spectral profiles represent the center of gravity of unknown high scoring de novo reconstructions (spectral dictionaries). This makes computing spectral profiles challenging because in many cases spectral dictionaries cannot be explicitly generated (11). This study extends Kim et al. (11) by showing how to compute the spectral profile of any spectrum without explicitly generating its spectral dictionary. We further show how to use spectral profiles for generating reliable gapped peptides.

The difficult challenge in de novo spectral interpretations is how to figure out which ion type every peak represents (e.g. how to distinguish b-series peaks from y-series peaks) and how to analyze the widely varying intensities in a single probabilistic framework. The spectral profile collapses all possible ion type interpretations and varying intensities into a single ion type (b-ion) with rigorously defined probability. In contrast to...
real MS/MS spectra (that contain peaks corresponding to b- and y-ions, various neutral losses, etc.), spectral profiles only represent (putative) b-ions. In some sense, spectral profiles represent a trade-off between (hard-to-interpret but compact) real spectra and (easy-to-interpret but huge) spectral dictionaries. We emphasize that spectral profiles are different from “scored spectra” (e.g. sequence spectra (14, 15) or prefix residue mass spectra (1)) that are commonly used for de novo sequencing and MS/MS database searches. Although profile probabilities are global (i.e. they take into account complex dependences between all peaks in the spectrum), scored spectra take into account only a few local satellite peaks explaining a given mass.

Similar to the diverse applications of motif profiles, spectral profiles have a multitude of applications that we describe below. Fig. 2 illustrates recently implemented alternative approaches to peptide identification: peptide sequence tag approaches (1, 2, 16, 17) and full-length de novo reconstruction approaches (7, 8, 11, 18) (see also lookup peak approach (19)). Although these approaches significantly speed up conventional peptide identification tools, each of them presents certain challenges, leading to deteriorating performance on long (15+–aa) peptides. Most of these approaches do not automatically adjust to varying spectral qualities or different peptide lengths. For example, InsPecT generates the same number of tags for every spectrum, although a more sensible approach would be to generate a larger number of tags for long peptides (tag generation deteriorates for longer peptides) or for low quality spectra. Although MS-Dictionary (11) generates an adaptive but large number of full-length reconstructions (for both high and low quality spectra), dictionaries of spectra of long peptides may become so large that their generation becomes impractical. To overcome this problem, we show how to quickly construct spectral profiles of even huge dictionaries without explicitly generating them.

MS-Profile currently works in two modes (Fig. 3). In the first mode, the input is an MS/MS spectrum and a spectral probability threshold (described below), and the output is a spectral profile. In the second mode, the constructed spectral profile, in addition to a de novo reconstruction, and a Min-Probability threshold (described below) serve as an input, and the output is a gapped peptide. MS-Profile in the second mode represents a new de novo peptide sequencing tool that improves accuracy of de novo reconstructions produced by other tools (e.g. PepNovo+, PEAKS, or MS-Dictionary). In particular, it generates gapped peptides that can be used for mutation-tolerant database searches and speed up existing database search tools. MS-Profile is available both as open source software and as a Web server.
**Experimental Procedures**

*What is the Spectral Profile?—*For the sake of simplicity, we will first introduce the notion of a spectral profile under the assumption that amino acid masses are integers. Given a peptide $P_1 \ldots P_m$, we define its prefix masses as a series $\text{mass}(P_1), \text{mass}(P_2), \ldots, \text{mass}(P_m)$, where $\text{mass}(P_i) = k$ is defined as the parent mass. We further represent the peptide $P_1 \ldots P_m$ as a k-mer boolean vector $P = x_1 \ldots x_k$, where $x_i = 1$ if $P_i$ represents a prefix mass and $x_i = 0$ otherwise (see Refs. 11, 20, and 21) for applications of boolean spectra and peptides.

Given a set of boolean peptides $\text{Dictionary} = \{P_1, \ldots, P_m\}$, we define the spectral profile as simply the center of gravity of all peptides (boolean vectors) in the set, i.e. Profile(Dictionary) $= 1/m \sum_{i=1}^{m} P_i$. This definition assumes that all peptides in the Dictionary are equally likely.

Kim *et al.* (11) introduced the notion of spectral dictionary and described an MS-Dictionary approach to peptide identification. Given a spectrum $\text{Spectrum}$ and a score threshold $\text{Threshold}$, Dictionary(Spectrum, Threshold) is defined as the set of all peptides with scores above the Threshold. We define the spectral profile Profile(Spectrum, Threshold) as Profile(Dictionary(Spectrum, Threshold)).

When the Dictionary is explicitly given, computing Profile(Dictionary) amounts to computing the center of gravity of k-dimensional boolean vectors from Dictionary. Although MS-Dictionary (11) is capable of quickly generating spectral dictionaries for short peptides (less than 15 aa), the spectral dictionaries of spectra of long peptides are so large (even for sensible choices of Threshold) that MS-Dictionary becomes impractical. For example, for a typical spectrum of a 15-aa long peptide, the spectral dictionary consists of $\sim 4 \times 10^9$ high scoring peptides that would typically result in statistically significant database hits (11). Below we show how to quickly generate spectral profiles of such huge dictionaries without explicitly generating the dictionary. MS-Profile takes only $\sim 0.2$ s to generate the spectral profiles even for spectra of long peptides. Thus MS-Profile bypasses the need to explicitly generate large spectral dictionaries that limited applications of MS-Dictionary in the case of long peptides.

**Computing Spectral Profiles**—The transformation of spectra into spectral profiles can be done efficiently by the forward-backward dynamic programming algorithm (22). For the sake of simplicity, we first represent a spectrum with parent mass $k$ as a boolean spectrum $S = s_1 \ldots s_k$ where $s_i = 1$ if there is a peak at mass $i$ in the spectrum and $s_i = 0$ otherwise. This representation assumes that spectra are capable of quickly generating spectral dictionaries for short peptides (less than 15 aa), the spectral dictionaries of spectra of long peptides are so large (even for sensible choices of Threshold) that MS-Dictionary becomes impractical. For example, for a typical spectrum of a 15-aa long peptide, the spectral dictionary consists of $\sim 4 \times 10^9$ high scoring peptides that would typically result in statistically significant database hits (11). Below we show how to quickly generate spectral profiles of such huge dictionaries without explicitly generating the dictionary. MS-Profile takes only $\sim 0.2$ s to generate the spectral profiles even for spectra of long peptides. Thus MS-Profile bypasses the need to explicitly generate large spectral dictionaries that limited applications of MS-Dictionary in the case of long peptides.

**Computing Spectral Profiles**—The transformation of spectra into spectral profiles can be done efficiently by the forward-backward dynamic programming algorithm (22). For the sake of simplicity, we first represent a spectrum with parent mass $k$ as a boolean spectrum $S = s_1 \ldots s_k$ where $s_i = 1$ if there is a peak at mass $i$ in the spectrum and $s_i = 0$ otherwise. This representation assumes that spectra are capable of quickly generating spectral dictionaries for short peptides (less than 15 aa), the spectral dictionaries of spectra of long peptides are so large (even for sensible choices of Threshold) that MS-Dictionary becomes impractical. For example, for a typical spectrum of a 15-aa long peptide, the spectral dictionary consists of $\sim 4 \times 10^9$ high scoring peptides that would typically result in statistically significant database hits (11). Below we show how to quickly generate spectral profiles of such huge dictionaries without explicitly generating the dictionary. MS-Profile takes only $\sim 0.2$ s to generate the spectral profiles even for spectra of long peptides. Thus MS-Profile bypasses the need to explicitly generate large spectral dictionaries that limited applications of MS-Dictionary in the case of long peptides.

**Computing Spectral Profiles**—The transformation of spectra into spectral profiles can be done efficiently by the forward-backward dynamic programming algorithm (22). For the sake of simplicity, we first represent a spectrum with parent mass $k$ as a boolean spectrum $S = s_1 \ldots s_k$ where $s_i = 1$ if there is a peak at mass $i$ in the spectrum and $s_i = 0$ otherwise. This representation assumes that spectra are capable of quickly generating spectral dictionaries for short peptides (less than 15 aa), the spectral dictionaries of spectra of long peptides are so large (even for sensible choices of Threshold) that MS-Dictionary becomes impractical. For example, for a typical spectrum of a 15-aa long peptide, the spectral dictionary consists of $\sim 4 \times 10^9$ high scoring peptides that would typically result in statistically significant database hits (11). Below we show how to quickly generate spectral profiles of such huge dictionaries without explicitly generating the dictionary. MS-Profile takes only $\sim 0.2$ s to generate the spectral profiles even for spectra of long peptides. Thus MS-Profile bypasses the need to explicitly generate large spectral dictionaries that limited applications of MS-Dictionary in the case of long peptides.

Spectral Probability

| Parameter | Value   |
|-----------|---------|
| MinProbability | 0.5     |

**RESULTS**

**Data Set**—We used the Standard Protein Mix database consisting of 1.1 million spectra generated from 18 proteins using eight different mass spectrometers (24). For this study, we considered only the charge 2 spectra generated by Thermo Electron LTQ where 1388 peptides of length between 7 and 20 are reliably identified with false discovery rate 2.5% using Sequest (3) and PeptideProphet (25) in the search against the Haemophilus influenzae database appended with sequences of the 18 proteins (567,460 residues). Although this study focuses on doubly charged spectra, MS-Profile can also be applied to MS/MS spectra of higher charges as long as an additive scoring model for highly charged MS/MS spectra is available.

For each peptide, we randomly selected one representative spectrum and formed a data set of 1388 PSMs grouped by the length of their peptide identifications. To avoid computational artifacts introduced by errors in the parent mass, the parent masses of the spectra are corrected according to the Sequest identifications. Below we refer to this data set as the Standard data set. Throughout the paper we measure accuracy of a de novo sequencing tool as the percentage of spectra with error-free reconstructions among all spectra in the Standard data set.

Fig. 5 shows the distribution of spectral probabilities (false positive rates) of the Standard data set. Most PSMs (91%) have spectral probabilities lower than $10^{-8}$. We used $10^{-8}$ as the spectral probability threshold to generate spectral profiles.

Table I shows the results of de novo peptide sequencing of the Standard data set with PEAKS, PepNovo+, and MS-Dictionary. PEAKS and MS-Dictionary correctly reconstructed peptides for less than 30% of the spectra, and the accuracy of both tools greatly deteriorates as the peptide length increases. PepNovo+ reported shorter de novo reconstructions (especially for spectra of long peptides) by allowing gaps in the start and the end of the peptides, resulting in accuracy better than that of the other tools. Below we show that MS-Profile improves the accuracy of these tools at the cost of a small reduction in the length of reconstructed peptides.

**De Novo Sequencing of Gapped Peptides**—De novo peptide sequencing algorithms usually correctly recover some amino acids within a peptide and misinterpret others. The key challenge is to figure out which portions of the peptide are reconstructed incorrectly and to limit reconstructions to highly accurate portions. Gapped peptide reconstruction addresses this challenge by reporting only reliably reconstructed regions of the peptide.

Given a Peptide $x_1 \ldots x_n$, a Profile $f_1 \ldots f_n$, and a parameter MinProbability, we define GappedPeptide(Peptide,
Profile,MinProbability=g₁,⋯,gₖasgᵢ=xᵢiffᵢ≥MinProbabilityandgᵢ=0otherwise.Fig.1showsaspectralprofileforthespectrumofpeptideSTVAGESGSADTVRandincorrectde novo reconstructionSSLAGEGSADTVR. Oncan noticethat alldifferentvaluesformostprefixmassesinSTVAGESGSADTVRare relatively high (0.207, 0.084, 0.475, 0.518, 0.310, 0.522, 0.791, 0.718, 0.730, 0.323, 0.149, and 0.353) the profile value for one prefix mass falls below 0.1. This low profile value points to an unreliable portion of the reconstruction. Converting peptideSTVAGESGSADTVRinto a gapped peptide (with MinProbability=0.1) results in a correct gapped peptideS[200]AGESGSADTVR.IncreasingMinProba-bility to 0.2 results in a shorter gapped peptideS[200]AGESGSAD[200]R.

MS-Profiles generates gapped peptides as follows. For each spectrum, it first constructs the spectral profile and generates optimal de novo reconstructions by backtracking its forward matrix. Indeed because MS-Profile uses the MS-Dictionary scoring (11), the reconstructions are the same as reconstructions generated by MS-Dictionary. Both PEAKS and MS-Dictionary may generate (a small number of) multiple optimal reconstructions, and we first convert them into a single consensus reconstruction. For example, the set of reconstructionsYWAGELTR,YWASVLTR,YWAPSLTR,andYWAGLTRLwillbeconvertedintoa single consensus reconstructionYWAs[186]LTRby retaining only the prefix masses present in all reconstructions. Next MS-Profile discards all prefix masses in the consensus reconstruction whose corresponding profile values are below MinProbability as described above. The remaining prefix masses represent the gapped peptide generated by applying MS-Profile to MS-Dictionary (referred to as MS-Profile(MS-Dictionary)). Fig. 6 compares the accuracy of de novo reconstructions generated by MS-Dictionary and the gapped peptide generated by MS-Profile(MS-Dictionary). Applying MS-Profile increases the percentage of correct reconstructions from 28 to 42% while decreasing the average length of reconstructions from 12.8 to 9.1 amino acids when MinProbability = 0.1. We remark that the Standard data set contains some low quality spectra that are nearly impossible to reconstruct in de novo fashion. Supplemental Fig. S4 illustrates the performance of MS-Profile when the Standard data set is restricted to high quality spectra. Supplemental Fig. S5 illustrates similar comparisons for the different MinProbability thresholds. One can increase the accuracy by increasing the MinProbability threshold. For example, when MinProbability = 0.2, the accuracy increases to 50% while the average length of gapped peptide decreases to 7.9. When MinProbability = 0.3, the accuracy increases to 54% while the average length of gapped peptide becomes 7.2.

Peptide length | Accuracy | Length | Accuracy | Length | Accuracy | Length
---|---|---|---|---|---|---
7–8 | 0.59 | 8.1 | 0.65 | 7.8 | 0.54 | 7.8
9–10 | 0.33 | 10.0 | 0.54 | 9.3 | 0.40 | 9.9
11–12 | 0.27 | 12.1 | 0.47 | 10.4 | 0.31 | 12.2
13–14 | 0.12 | 14.1 | 0.36 | 12.0 | 0.14 | 14.2
15–16 | 0.10 | 16.0 | 0.34 | 13.2 | 0.12 | 16.1
17–18 | 0.07 | 16.9 | 0.29 | 14.1 | 0.02 | 18.3
19–20 | 0.05 | 19.0 | 0.38 | 14.0 | 0.04 | 20.8
Total | 0.26 | 12.6 | 0.46 | 11.0 | 0.28 | 12.8

PEAKS (online 2.0), PepNovo+ (released July 24, 2008), and MS-Dictionary (released November 7, 2007) were run with parent mass and fragment mass tolerances of 0.5 Da, fixed modification of Cys + 57, no optional modifications, and without any enzyme preference. In contrast to PEAKS and MS-Dictionary, PepNovo+ allows gaps at the start/end of peptides thus giving PepNovo+ significant leverage when it comes to the reported accuracy of reconstruction. Although MS-Dictionary is designed for generating spectral dictionaries (rather than ensuring that the correct reconstruction has the top score), it can be used in de novo mode as well (it has slightly higher accuracy than PEAKS while generating slightly longer peptides). PEAKS and MS-Dictionary have a tendency to output reconstructions that are longer than the correct peptides (e.g. for peptides of length 11–12, the average length of PEAKS and MS-Dictionary reconstructions is 12.1 and 12.2, respectively). Accuracy of each tool is defined as the percentage of the error-free reconstructions among all reconstructions for the Standard data set.
PepNovo + allows users to generate up to 2000 reconstructions per spectrum. When multiple reconstructions are generated, the probability of at least one of them being correct increases. For each reconstruction, we generate a gapped peptide using MS-Profile (PepNovo +), because different PepNovo + reconstructions may correspond to the same gapped peptide, the number of gapped peptides generated by MS-Profile is typically smaller than the original number of PepNovo + reconstructions. Supplemental Table S1 illustrates that although the number of gapped peptides generated by MS-Profile is 3-15 times smaller than the number of PepNovo + reconstructions, the length of the reconstructed gapped peptides is typically sufficient to ensure a unique database hit. Fig. 8 compares accuracy and length of peptides and gapped peptides generated by PepNovo + and MS-Profile for the top 100 and the top 1000 reconstructions. Again MS-Profile outperforms PepNovo + while generating much smaller numbers of gapped peptides.

The improved performance of MS-Profile in generating gapped peptides suggests that it can be used for database filtration in the same way as peptide sequence tags are used in InsPeCT (1). For the Standard data set, we ran InsPeCT to generate 1, 10, and 25 tags of lengths 3 and 4 and measured for how many spectra InsPeCT generates at least one correct tag (Fig. 9). The same number of gapped peptides are generated by MS-Profile. It turned out that the best gapped peptide is longer and more accurate than the best tag of length 3 (the gapped peptide is correct for 65% of spectra, whereas the best 3-aa long tag is correct for 44% of spectra). Also top 10 and 25 gapped peptides are roughly as accurate as the same number of tags of length 3.
For 83% of spectra, at least one of the top 10 gapped peptides is correct, whereas for 80% of spectra, at least one of the top 10 tags of 3 aa is correct. For 86% of spectra, at least one of the top 25 gapped peptides is correct, whereas for 88% of spectra, at least one of the top 25 tags of 3 aa is correct. This is surprising because gapped peptides generated by MS-Profile(PepNovo/H11001) represent a much better filter for database search than InsPecT tags. To test the filtering efficiency, we matched the top gapped peptide of each spectrum and its top 3-aa tag against the Swiss-Prot database (release 56.4, 145 million residues) counting the number of false matches to the database. Although 90% of gapped peptides have no false matches, only 29% of tags have no false match. The average number of false matches is 1.6 for gapped peptides, 50 times smaller than 80.3 false tag matches on average. The average number of false matches is a key parameter in filtration-based MS/MS searches because...
it is roughly proportional to the time required for peptide identification (1). Therefore, a 50-fold reduction in the number of false matches can potentially translate into a 50-fold speedup as compared with (already fast) InsPecT. The contrast between gapped peptides and tags is particularly pronounced in searches against very large databases like proteogenomic six-frame translation searches of the repeat-masked human genome of size 2.7 billion residues (11). Gapped peptides longer than 8 aa (63% of spectra in the Standard data set) are expected to have only 0.24 false matches in this database, whereas 3-aa tags are expected to have 1400 false matches on average.

This comparison suggests that MS-Profile can significantly improve on previous filtration approaches to MS/MS database searches. In contrast to peptide sequence tags (that typically have many false hits in a database), gapped peptides typically have few false hits (if any) thus speeding up the database searches. We comment that use of gapped seeds in traditional BLAST-like genomics searches is well studied (26).

Evaluating Spectral Profile Probabilities—Some de novo sequencing programs output the reliability of predicted amino acids. For example, PepNovo+ defines features that reflect the reliability of each predicted amino acid and converts the feature vectors into probabilities (27). PEAKS recently added a similar function that computes the reliability of an amino acid $a$ by locally permuting the reconstruction around $a$, computing the score difference between the original and permuted reconstructions and using the prelearned distribution of the difference to assign the reliability of $a$ (28). MS-Profile differs from these tools because instead of learning it rigorously computes a probability that a prefix mass is present in a high scoring de novo peptide reconstruction.

We show that the spectral profile probabilities approximate the empirical accuracy of the prefix mass (represented by the profile peak) being correct. To compute the accuracy of the profile value $p$ (for $p = 0.1, 0.2, \ldots, 0.9, 1.0$), we bundled all the profile peaks with values between $p - 0.05$ and $p + 0.05$ and measured the fraction of correct peaks among them. If the empirically computed fraction of correct peaks of the profile value $p$ is close to $p$ then our estimate of profile probabilities is unbiased. Fig. 10 shows that it is indeed the case: the empirical accuracy of the profile peaks with probability $p$ is slightly above $p$. The slightly higher empirical accuracy (as compared with profile values) is likely a consequence of using the same spectral probability threshold of $10^{-8}$ for all spectra, whereas in reality most PSMs have much lower spectral probabilities (Fig. 5).

**DISCUSSION**

Although peptide sequence tags were first proposed in 1994 (29), it took 10 years for this idea to become an integral part of the new generation of fast MS/MS database search tools (1, 2). It took such a long time because a seemingly simple problem of generating accurate sequence tags turned out to be more difficult than originally thought. We demonstrated that gapped peptides occupy an important niche between long but inaccurate full-length peptide reconstructions and short but more accurate peptide sequence tags. This niche provides certain advantages because gapped peptides represent a more stringent filter that may enable very fast MS/MS database searches that in many cases will amount to a simple lookup in a database. Spectral profiles reveal poor quality spectra (or poor quality regions within long peptides) that other methods have difficulties analyzing. MS-Profile follows a different route to error-tolerant peptide identifications than OpenSea (7) and SPIDER (8). Instead of trying to generate (unreliable) full-length reconstructions and approximately matching them against the database, MS-Profile generates reliable gapped peptides and matches them against the database exactly.
Some de novo sequencing tools such as Lutefisk (30), PEAKS (12), and PepNovo+ (10) can generate gapped peptides typically trimming the full-length peptides in the beginning/end. Even when internal gaps are allowed (Lutefisk and PEAKS), they are limited to gaps of 2 aa or shorter. For long peptides where multiple consecutive peaks are missing, it is hard to generate correct gapped peptides when only short gaps are allowed. On the other hand, PepNovo+ improves on these tools by allowing long gaps in the start/end of the peptides. As a result, PepNovo+ has a tendency to generate incorrect solutions when it tries to reconstruct all amino acids in the middle. To the best of our knowledge, MS-Profile is the only program that allows both short and long gaps regardless of the position. Also MS-Profile can convert any de novo reconstructions into gapped peptides thus making it a useful addition to various de novo peptide sequencing tools.
