Abstract—Signal decomposition is a classical problem in signal processing, which aims to separate an observed signal into two or more components each with its own property. Usually each component is described by its own subspace or dictionary. Extensive research has been done for the case where the components are additive, but in real world applications, the components are often non-additive. For example, an image may consist of a foreground object overlaid on a background, where each pixel either belongs to the foreground or the background. In such a situation, to separate signal components, we need to find a binary mask which shows the location of each component. Therefore it requires to solve a binary optimization problem. Since most of the binary optimization problems are intractable, we relax this problem to the approximated continuous problem, and solve it by alternating optimization technique, which solves the mask and the subspace projection for each component, alternatingly and iteratively. We show the application of the proposed algorithm for three applications: separation of text from background in images, separation of moving objects from a background undergoing global camera motion in videos, separation of sinusoidal and spike components in one dimensional signals. We demonstrate in each case that considering the non-additive nature of the problem can lead to significant improvement.

Index Terms—Signal Decomposition, Alternating Optimization, Mixed Integer Programming, ADMM, Segmentation.

I. INTRODUCTION

Signal decomposition is an important problem in signal processing and has a wide range of applications. Image segmentation and audio source separation are some of the applications of signal decomposition. For example in image segmentation the goal is to decompose the image into several components such that each one represents the same content or semantic information.

Different algorithms have been proposed in the past, where each one of them looked at signal decomposition from a different perspective. Perhaps, Fourier transform [1] is one of the earliest work on signal decomposition where the goal is to decompose a signal into different frequencies. Using the same methodology, many algorithms have been proposed for high and low frequency components. Wavelet and multi-resolution decomposition are also another big group of methods which are designed for signal decomposition in both time and frequency domain [2]-[3]. In the more recent works, there have been many works on low-rank decomposition, where in the simplest case the goal is to decompose a signal into two components, one being low rank, another being sparse. Usually the nuclear and \( \ell_1 \) norms are used to promote low-rankness and sparsity respectively. To name some of the promising works along this direction, in [8], Candes et al proposed a low-rank decomposition for matrix completion. In [9], Peng et al proposed a sparse and low-rank decomposition approach with application for robust image alignment. A similar approach has been proposed by Zhang [10] for transform invariant low-rank textures. This approach has also been used for background subtraction in videos [11].

Most of the prior approaches for signal decomposition consider additive model, i.e. the signal components are added in a mathematical sense to generate the overall signal, as:

\[
x = \sum_{k=1}^{K} x_k
\]  

Here \( x \) denotes a vector in \( \mathbb{R}^N \). Assuming we have some prior knowledge about each component, we can form an optimization problem as in Eq (2) to solve the signal decomposition problem. Here \( \phi_k \) is the regularization term that encodes the prior knowledge about the \( i \)-th signal component.

\[
\min_{w_k, x_k} \sum_{k=1}^{K} \phi_k(x_k), \quad \text{s.t.} \quad \sum_{k=1}^{K} x_k = x
\]  

In this work, we investigate a different class of signal decomposition, where the signal components are overlaid on top of each other, rather than simply added. In other word, at each signal element only one of the signal components could be active (non-zero). We can formulate this as:

\[
x = \sum_{k=1}^{K} w_k \circ x_k \quad \text{s.t.} \quad w_k \in \{0, 1\}^N, \quad \sum_{k=1}^{K} w_k = 1
\]  

where \( \circ \) denotes the element-wise product [12], and \( w_k \)'s are the binary masks, where at each element one and only one of the \( w_k \)'s is 1, and the rest are zero. In our work, we assume that each component can be represented with a known subspace/dictionary. In this case, the main goal is to find the binary mask \( w_k \) which denotes the support of each signal components. This happens in many signal decomposition applications, such as image segmentation, text extraction from images, and face detection with occlusion.

To show an example application of this problem, consider the left image in Figure 1, where some text is overlaid on top
of a textured background using a binary mask as shown in the right figure. As it can be seen from this image, the pixel values at the text locations are not affected by the background image.

![Text over Texture](image1)

**Fig. 1:** The overlaid image, and the corresponding binary mask for foreground text

Different algorithms can be used to separate the text from background, such as clustering-based algorithms, sparse-decomposition based methods, and morphological operations [13]-[20]. Figure 2 denotes a comparison between the segmentation results using hierarchical k-means approach [14], sparse decomposition [17]-[18], and the proposed algorithm in this work. As we can see, each of the previous approaches have their own difficulties. For example, clustering-based scheme would have difficulty separating text from background in the case where the text has a similar color to the background. The sparse-decomposition based model misses some part of the text, while detecting some part of the background as text. The proposed algorithm performed very well in separating the text from the background texture. Note that the main case where the text has a similar color to the background. would have difficulty separating text from background in the

![Text over Texture](image2)

**Fig. 2:** The top-right, bottom-left and bottom-right images denote the segmentation map by hierarchical clustering, sparse decomposition, and the proposed algorithm respectively.

The structure of the rest of this paper is as follows: Section II presents the problem formulation. Section III describes the augmented Lagrange multiplier to solve the binary mask estimation. In Section IV, we show the application of this approach for motion segmentation. The experimental results, and the applications are provided in Section V, and the paper is concluded in Section VI.

## II. Problem Formulation

As discussed earlier, we consider overlaid signal decomposition model where the signals are added as $x = \sum_{k=1}^{K} w_k \circ x_k$, where $\circ$ denotes the element-wise product, and $w_k$’s are the binary masks, where at each element one and only one of the $w_k$’s is 1, and the rest are zero.

If these components have different characteristics, it would be possible to separate them to some extent. One possible way is to form an optimization problem as below:

$$
\min_{w_k \in \{0,1\}^N, \sum_{k=1}^{K} w_k = 1, \sum_{k=1}^{K} w_k \circ x_k = x} \sum_{k=1}^{K} \phi_k(x_k) + \psi_k(w_k)
$$

where $\phi_k$ and $\psi_k$ encodes our prior knowledge about each component and its corresponding mask respectively, and the constraint $\sum_{k=1}^{K} w_k = 1$ makes sure that at each point only one of the signal components is active.

To further simplify the problem, we assume that each component $x_k$ has a sparse representation using some proper dictionary/bases $P_k$. To make the formulation easier to explain, we look at the decomposition into two components. In this case we can drop the index subscript, and get:

$$
x = (1 - w) \circ (P_1 \alpha_1) + w \circ (P_2 \alpha_2)
$$

where $w \in \{0,1\}^N$, and $P_k$ is $N \times M_k$ matrix, where each column denotes one of the basis functions from the corresponding subspace/dictionary, and $M_k$ is the number of basis functions for component $k$.

Note that, in an alternative approach this can be written as:

$$
x = (I - W) P_1 \alpha_1 + WP_2 \alpha_2
$$

where $W$ is a diagonal matrix with the vector $w$ on its main diagonal (shown as $W = \text{diag}(w)$). If a diagonal element is 1, the corresponding element belongs to component 2, and otherwise to component 1.

The decomposition problem in Eq. (6) is a highly ill-posed problem. Therefore we need to impose some prior on each component, and also on $w$ to be able to perform this decomposition. We assume that each component has a sparse representation with respect to its own subspace, but not with respect to the other one. We also assume that the second component is sparse and connected.

To promote sparsity of the second component, we add the $\ell_0$ norm of $w$ to the cost function (note that $w$ corresponds to the support of the second component). To promote connectivity, we can either add the group sparsity or total variation of $w$ to the cost function. Here we use total variation. The main reason is that for group sparsity, it is not very clear what is the best way to define groups, as the foreground pixels...
could be connected in any arbitrary direction, whereas total variation can deal with this arbitrary connectivity more easily.

We can incorporate all these priors in an optimization problem as shown below:

\[
\begin{align*}
\min_{w, \alpha_1, \alpha_2} & \quad \frac{1}{2} \| x - (1 - w) \circ P_1 \alpha_1 - w \circ P_2 \alpha_2 \|_2^2 + \lambda_1 \| w \|_1 + \lambda_2 \text{TV}(w) \\
\text{s.t.} & \quad w \in \{0, 1\}^N, \| \alpha_1 \|_0 \leq K_1, \| \alpha_2 \|_0 \leq K_2
\end{align*}
\]

(7)

Total variation of 1D signals \( w = [w_1, w_2, \ldots, w_N] \) is straightforward, and can be defined as:

\[
TV(w) = \sum_{n=1}^{N-1} |w_{n+1} - w_n| = \| D_1 w \|_1
\]

(8)

where \( D \) is a \((N - 1) \times N\) matrix as below:

\[
D = \begin{bmatrix}
1 & -1 & 0 & \ldots & 0 \\
0 & 1 & -1 & \ldots & 0 \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
0 & 0 & \ldots & 1 & -1
\end{bmatrix}
\]

For 2D signals \( w = [w_{i,j}, i = 1, \ldots, I, j = 1, \ldots, J] \), we can either use the isotropic or the anisotropic version of 2D total variation \([21]\). To make our optimization problem simpler, we have used the anisotropic version in this algorithm, which is defined as:

\[
TV(w) = \sum_{i,j} |w_{i+1,j} - w_{i,j}| + |w_{i,j+1} - w_{i,j}|
\]

(9)

After converting the 2D blocks into 1D vector, we can denote this total variation as below:

\[
TV(w) = \| D_x w \|_1 + \| D_y w \|_1 = \| Dw \|_1
\]

(10)

where \( D_x \) and \( D_y \) are the horizontal and vertical difference operator matrices, and \( D = [D_x', D_y']' \).

The problem in (7) involves multiple variables, and is not tractable, both because of the \( \| w \|_0 \) term in the cost function and also the binary nature of \( w \). We relax these conditions to be able to solve this problem in an alternating optimization approach. We replace the \( \| w \|_0 \) in the cost function with \( \| w \|_1 \), and also relax the \( w \in \{0, 1\}^N \) condition to \( w \in [0, 1]^N \) (which is known as linear relaxation in the mixed integer programming). Then we will get the following optimization problem:

\[
\begin{align*}
\min_{w, \alpha_1, \alpha_2} & \quad \frac{1}{2} \| x - (1 - w) \circ P_1 \alpha_1 - w \circ P_2 \alpha_2 \|_2^2 + \lambda_1 \| w \|_1 + \lambda_2 \| Dw \|_1 \\
\text{s.t.} & \quad w \in [0, 1]^N, \| \alpha_1 \|_0 \leq K_1, \| \alpha_2 \|_0 \leq K_2
\end{align*}
\]

(11)

This problem can be solved with different approaches, such as majorization minimization, alternating direction method, and random sampling approach \([22, 26]\). Here we present an algorithm based on alternating direction method of Lagrange multipliers (ADMM) \([22]\) to solve this problem.

### III. The Proposed Optimization Framework

ADMM is a popular algorithm which combines superior convergence properties of method of multiplier and decomposibility of dual ascent. To solve the optimization problem in Eq (12) with Augmented Lagrangian algorithm, we first introduce two auxiliary random variables as:

\[
\begin{align*}
\min_{w, \alpha_1, \alpha_2} & \quad \frac{1}{2} \| x - (1 - w) \circ P_1 \alpha_1 - w \circ P_2 \alpha_2 \|_2^2 + \lambda_1 \| y \|_1 + \lambda_2 \| z \|_2 \\
\text{s.t.} & \quad w \in [0, 1]^N, y = w, z = Dw, \| \alpha_1 \|_0 \leq K_1, \| \alpha_2 \|_0 \leq K_2
\end{align*}
\]

(12)

To solve this problem, we form the augmented Lagrangian as below:

\[
\begin{align*}
L(\alpha_1, \alpha_2, w, y, z, u_1, u_2) = & \quad \frac{1}{2} \| x - (1 - w) \circ P_1 \alpha_1 - w \circ P_2 \alpha_2 \|_2^2 \\
& + \lambda_1 \| y \|_1 + \lambda_2 \| z \|_2 + u_1^T (w - y) + u_2^T (Dw - z) + \frac{\rho_1}{2} \| w - y \|_2^2 \\
& + \frac{\rho_2}{2} \| Dw - z \|_2^2
\end{align*}
\]

(13)

Now we can solve this problem by minimizing the Augmented Lagrangian w.r.t. to primal variables \((\alpha_1, \alpha_2, w, y \text{ and } z)\) and using dual ascent for dual variables \((u_1, u_2)\). For updating the variables \(\alpha_1 \) and \(\alpha_2\), we first ignore the constraints and take the derivative of \(L\) w.r.t. them and set it to zero. Then we project the solution on the constraint \(\| \alpha_i \|_0 \leq K_i\) by keeping the \(K_i\) largest components. Since the cost function is symmetric in \(\alpha_1 \) and \(\alpha_2\), we only show the solution for \(\alpha_2\) here.

\[
\alpha_2 = \arg \min_{\alpha_2} L(\alpha_1, \alpha_2, w, y, z, u_1, u_2) = \arg \min_{\alpha_2} \| x - (1 - w) \circ P_1 \alpha_1 - w \circ P_2 \alpha_2 \|_2^2
\]

\[
\arg \min_{\alpha_2} \| x - (1 - w) \circ P_1 \alpha_1 - w \circ P_2 \alpha_2 \|_2^2 = \arg \min_{\alpha_2} \| x - (I - W) P_1 \alpha_1 - W P_2 \alpha_2 \|_2^2
\]

\[
\nabla_{\alpha_2} L = \frac{P_2 W^T (W P_2 \alpha_2 + (I - W) P_1 \alpha_1 - x)}{0} \Rightarrow \alpha_2 = (P_2 W^T W P_2)^{-1} P_2 W^T (x - (I - W) P_1 \alpha_1)
\]

Now we keep the \(K_2\) largest components of the above \(\alpha_2\), which is denoted by: \(\alpha_2^* = \Pi_{\text{top-}K_2}(\alpha_2)\).

We now show the optimization with respect to \(w\). We solve this optimization by first ignoring the constraint, and then projecting the optimal solution of the cost function onto the feasible set \((w \in [0, 1]^N)\). It basically follows the same methodology, we just need to notice that diag\((w) P_2 \alpha_2\) is the same as diag\((P_2 \alpha_2) w\). Therefore we will get the following optimization for \(w\):

\[
\begin{align*}
w = \arg \min_w & \quad \frac{1}{2} \| x - \text{diag}(P_1 \alpha_1)(1 - w) - \text{diag}(P_2 \alpha_2) w \|_2^2 + u_1^T (w - y) + u_2^T (Dw - z) + \frac{\rho_1}{2} \| w - y \|_2^2 \\
& + \frac{\rho_2}{2} \| Dw - z \|_2^2
\end{align*}
\]

We can rewrite this problem as:

\[
w = \arg \min_w \frac{1}{2} \| h - Cw \|_2^2 + \frac{\rho_1}{2} \| w - y \|_2^2 + \frac{\rho_2}{2} \| Dw - z \|_2^2 + u_1^T (w - y) + u_2^T (Dw - z)
\]
where $C = \text{diag}(P_2\alpha_2) - \text{diag}(P_1\alpha_1) = \text{diag}(P_2\alpha_2 - P_1\alpha_1)$, and $h = x - P_1\alpha_1$. If we take the derivative w.r.t. $w$ and set it to zero we will get:

$$C^t(Cw - h) + \rho_1(w - y) + \rho_2D^t(Dw - z) + u_1 + D^t u_2 = 0 \Rightarrow 
(C^tC + \rho_2D^tD + \rho_1I)w = C^t h + \rho_1 y + \rho_2 D^t z - u_1 - D^t u_2 \Rightarrow w = \Pi_{[1,1]}(C^t h + \rho_1 y + \rho_2 D^t z - u_1 - D^t u_2)
$$

where $M_w = (C^tC + \rho_2D^tD + \rho_1I)$. After finding $w$ using the above equation, we need to project them on the set $w \in [0,1]^n$, which basically maps any negative number to 0, and any number larger than 1 to 1. Denoting the projection operator by $\Pi_{[0,1]}$, the optimization solution of the $w$ step would be:

$$w = \Pi_{[1,1]}(C^t h + \rho_1 y + \rho_2 D^t z - u_1 - D^t u_2)) \quad (14)$$

The optimization w.r.t. $y$ and $z$ are quite simple, as they result in a soft-thresholding solution [27]. The overall algorithm is summarized in Algorithm 1.

**Algorithm 1** pseudo-code for variable updates of problem (12)

1: for $j = 1: T_{\text{max}}$
2: \begin{align*}
α^{j+1}_1 &= (P_1^t W_1^t W_2 P_1)^{-1}P_1^t W_1^t(x - W_2 \alpha^j_2) \quad (15a) \\
α^{j+1}_2 &= (P_2^t W_2^t P_2)^{-1}P_2^t W_2^t(I - W_1)P_1^t \alpha^{j+1}_1 \quad (15b) \\
\rho^{j+1} &= \Pi_{[1,1]}(C^t h^{j+1} + \rho_1 y^j + \rho_2 D^t z^j - u_1^j - D^t u_2^j) \quad (15c)
\end{align*}
3: $y^{j+1} = \text{soft}(\rho^{j+1}, \lambda_1/\rho_1)$
4: $z^{j+1} = \text{soft}(D\rho^{j+1}, \rho_2/\rho_2)$
5: $u^{j+1}_1 = \rho_1 y^{j+1} - y^{j+1}$
6: $u^{j+1}_2 = \rho_2 (D\rho^{j+1} - z^{j+1})$
7: end for
8: where $C = \text{diag}(P_2\alpha_2 - P_1\alpha_1)$, $h = x - P_1\alpha_1$.
9: and $M_w = (C^tC + \rho_2D^tD + \rho_1I)$

where $W_* = I - W$, and soft$(x, \lambda)$ denotes the soft-thresholding operator applied element-wise and defined as:

$$\text{Soft}(x, \lambda) = \text{sign}(x) \text{ max}(|x| - \lambda, 0)$$

IV. APPLICATION FOR ROBUST MOTION SEGMEMNTATION

One potential application of the proposed formulation is for moving object detection under global camera motion in a video, or essentially segmentation of a motion field into regions with global motion and object motions, respectively.

Suppose we use the homography mapping (also known as perspective mapping) to model the camera motion, where each pixel in the new frame is related to its position in the previous frame by:

$$x_{\text{new}} = \frac{a_1 + a_2 x + a_3 y}{1 + a_2 x + a_3 y} \quad (16a)$$
$$y_{\text{new}} = \frac{a_4 + a_5 x + a_6 y}{1 + a_7 x + a_8 y} \quad (16b)$$

Let $u = x_{\text{new}} - x$ and $v = x_{\text{new}} - x$, we can rewrite the above equation as:

$$(x + u)(1 + a_7 x + a_8 y) = (a_1 + a_2 x + a_3 y)$$
$$(y + v)(1 + a_7 x + a_8 y) = (a_4 + a_5 x + a_6 y)$$

For a given pixel $(x,y)$ and its motion vector $(u,v)$, we will get two equations for the homograph parameters $a = [a_1, \ldots, a_8]$, that can be written as:

$$\begin{bmatrix} 1 & x & y & 0 & 0 & 0 & -x(x+u) & -y(x+u) \\ 0 & 0 & 0 & 1 & x & y & -x(y+v) & -y(y+v) \end{bmatrix} a = \begin{bmatrix} x+u \\ y+v \end{bmatrix}$$

Using the equations at all pixels, we will get a matrix equation as:

$$Pa = b$$

Suppose $u(x,y)$ and $v(x,y)$ are given using some optical flow estimation algorithm. Then the goal is to find the global motion parameters and the set of pixels which do not follow the global motion. Note that here, $P$ will not be the same for different video frames, as it depends on the optical flow (which could be different for different frames). Assuming there are some outliers (corresponding to moving objects) in the video, we can use the model $b = (1 - w) \circ Pa + w \circ s$, where $w$ denotes the outlier pixels, and $s$ denotes the new location for the outlier pixels. If the outlier pixels belong to a single object with a consistent local motion, we can model $s$ as $s = P_2 \alpha_2$. However, in general, the outlier pixels may correspond to multiple foreground objects with different motions or different subregions of a single object (e.g. different parts of a human body) with different motions. Therefore, we do not want to model $s$ with a single parameterized motion. Rather we will directly solve for $s$ with a sparsity constraint. These considerations lead to the following optimization problem:

$$\min_{w, a, s} \frac{1}{2} \|b - (1 - w) \circ Pa - w \circ s\|_2^2 + \lambda_1 \|s\|_1$$
$$+ \lambda_2 \|w\|_1 + \lambda_3 \|Dw\|_1 \quad (17)$$

s.t. $w \in [0,1]^n$

Note that $b$, $P$, and $s$ in Eq (17) have two parts, one corresponding to the horizontal direction, and another part corresponding to vertical direction (denoted with subscripts $x$ and $y$ respectively). Therefore we can re-write this problem as:

$$\min_{w, a, s} \frac{1}{2} \|b_x - (1 - w) \circ P_x a - w \circ s_x\|_2^2 + \lambda_1 \|s_x\|_1 + \lambda_1 \|s_y\|_1$$
$$+ \lambda_2 \|w\|_1 + \lambda_3 \|Dw\|_1 \quad (18)$$

s.t. $w \in [0,1]^n$

This problem can be solved with ADMM. After solving this problem we will get the mask for the moving objects. Note that this approach works for other global motion models such as the affine mapping. In the extended version of this algorithm, we can directly work on a volume of $\tau$ frames to use the temporal information for mask extraction. In that case, the mask $w$ would also be a 3D tensor.

In the experimental result section, we provide the result of motion segmentation using the proposed algorithm.
V. EXPERIMENTAL RESULTS

In this section we provide the experimental study on the application of the proposed algorithm for 1D signals decomposition, image segmentation, and also motion segmentation. For each application, different sets of parameters are used, which are tuned on a validation data from the same task.

A. 1D signal decomposition

To illustrate the power of the proposed algorithm for non-additive decomposition, we first experiment with a toy example using 1D signals. We generate two 1D signals, each 256 dimensional, using different subspaces. The first signal is generated from a 10-dimensional sinusoid subspace, and the second component is generated from a 10-dimensional Hadamard subspace. We then generate a random binary mask with the same size as the signal, and added these two components using the mask as: $x = (1 - w) \odot x_1 + w \odot x_2$. The goal is to separate these two components, and estimate the binary mask. The signal components and binary mask for one example are shown in Figure 3.

![Image](image.png)

Fig. 3: The binary mask, and signal components

We then use the proposed model to estimate each signal component and extract the binary mask, and compare it with the signal decomposition under additive model. By additive model we mean the following optimization problem:

$$
\min_{\alpha_1, \alpha_2} \frac{1}{2} \| f - P_1 \alpha_1 - P_2 \alpha_2 \|_2^2 + \lambda_1 \| P_2 \alpha_2 \|_1 + \lambda_2 \text{TV}(P_2 \alpha_2)
\text{s.t.} \quad \| \alpha_1 \|_0 \leq k_1, \quad \| \alpha_2 \|_0 \leq k_2
$$

(19)

The estimated signal components and binary mask by each algorithm, for two examples are shown in Figure 4. In our experiment, the weight parameters for the regularization terms in Eq (12) are chosen to be, $\lambda_1 = 0.3$ and $\lambda_2 = 10$. The number of iterations for alternating optimization algorithm is chosen to be 20. As it can be seen the proposed algorithm achieves much better result than the additive signal model. This is what is expected, because the additive model could try to model some parts of the second component with the first subspace and vice versa.

B. Application in Text/Graphic Segmentation From Images

Next we test the potential of the proposed algorithm for the text and graphic segmentation from images. We perform segmentation on two different sets of images. The first one is on a dataset of screen content images, which consist of 332 image blocks of size 64x64, extracted from sample frames of HEVC test sequences for screen content coding [30], [31]. The second set of images are generated manually by adding text on top of other images.

We apply our algorithm on blocks of 64x64 pixels. We first convert each block into a vector of dimension 4096, and then apply the proposed algorithm. For the smooth background we use low-frequency DCT basis with $k_1 = 40$, and for the second component we use Hadamard basis with $k_2 = 8$. The weight parameters for the regularization terms are chosen to be $\lambda_1 = 10$ and $\lambda_2 = 0.2$, which are tuned by testing on a separate validation set of more than 50 patches. The number of iterations for alternating optimization algorithm is chosen to be 10. We compare the proposed algorithm with four previous algorithms; hierarchical k-means clustering in DjVu [14], SPEC [16], least absolute deviation fitting (LAD) [19], and sparsity based signal decomposition [17].

The results for 4 test images (each consisting of multiple 64x64 blocks) are shown in Figure 5. It can be seen that the proposed algorithm gives superior performance over DjVu and SPEC in all cases. There are also noticeable improvement over our prior works on LAD and sparse decomposition based image segmentation. We would like to note that, this dataset mainly consists of challenging images where the background and foreground have overlapping color ranges. For simpler cases where the background has a narrow color range that is quite different from the foreground, both DjVu and least absolute deviation fitting will work well.

In another experiment, we manually added text on top of an image, and tried to extract them using the proposed algorithm. Figure 6 shows the comparison between the proposed algorithm and the previous approaches. For this part we also provide the results derived by the method of sparse and low-rank decomposition [28], using the MATLAB implementation provided in [29]. To derive the foreground map using this approach, we threshold the absolute value of sparse component after decomposition. For all images, we see that the proposed method yields significantly better text segmentation.

We also provide the average precision, recall and F1 score achieved by different algorithms for the above sample images. The precision and recall are defined as in Eq. (20), where TP, FP and FN denote true positive, false positive and false negative respectively. In our evaluation, we treat the active elements of the binary mask as positive. The same holds for false negative and false positive. The balanced F1 score is
Fig. 4: The 1D signal decomposition results for two examples. The figures in the first column denote the original binary mask, first and second signal components respectively. The second and third columns denote the estimated binary mask and signal components using the proposed algorithm and the additive model signal decomposition, respectively.
defined as the harmonic mean of precision and recall, as it is shown in Eq (21).

\[
\text{Precision} = \frac{TP}{TP + FP}, \quad \text{Recall} = \frac{TP}{TP + FN} \tag{20}
\]

\[
F_1 = \frac{2 \times \text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \tag{21}
\]

The average precision, recall and F1 score by different algorithms are given in Table 1. As it can be seen, the proposed scheme achieves much higher precision and recall than hierarchical k-means clustering and sparse decomposition approach. We did not provide the results by SPEC [16] algorithm for these images, since the derived segmentation mask using SPEC was not satisfactory.

C. Application for Motion Segmentation

In this section, we demonstrate the application of the proposed algorithm for motion based object segmentation in
Fig. 6: Segmentation result for the text over texture images. The images in the first row denotes the original images. And the images in the second, third, forth and the fifth rows denote the foreground map by hierarchical k-means clustering [14], sparse and low-rank decomposition [8], sparse decomposition [17], and the proposed algorithm respectively.

TABLE I: Comparison of accuracy of different algorithms for text image segmentation for images in Fig 6.

| Segmentation Algorithm            | Precision | Recall | F1 score |
|-----------------------------------|-----------|--------|----------|
| Hierarchical Clustering [14]      | 66.5%     | 92%    | 77.2%    |
| Sparse and Low-rank [8]           | 54%       | 62.8%  | 57.7%    |
| Sparse Dec. with TV [17]          | 71%       | 91.7%  | 80%      |
| The proposed algorithm            | 95%       | 92.5%  | 93.7%    |

video. We assume the video undergoes global camera motion (modeled by a homography mapping) as well as localized object motion (modeled by a sparse component). The optical flow field between two frames can thus being modeled by a masked decomposition of the global motion and object motion.

To extract the optical flow, we use the optical flow implementation in [33], [34]. We then use the formulation in Eq (18), with $\lambda_1 = 1$, $\lambda_2 = 0.8$ and $\lambda_3 = 0.5$, to find both the global motion parameters and the object mask $w$. Note that the estimated $w$ from Eq (18) is a continuous mask where each element is in $[0,1]$, we threshold these values to derive the binary mask for foreground. We compare our work with the simple least squares fitting method where we use the following optimization problem to fit the homography model to the whole optical flow, and detect foreground pixels based on the error on the motion estimation.

$$
\min_a \frac{1}{2} \| b_x - P_x a \|^2 + \frac{1}{2} \| b_y - P_y a \|^2
$$

The motion segmentation results using the proposed algorithm, and the comparison with the least squares fitting for two videos are provided in Figure 7 and Figure 8. As we can see the proposed algorithm achieves better segmentation compared to the baseline. We would like to note that, this is a preliminary study to show the motion segmentation as one of the potential applications of this work, and the result could be much improved by using more accurate optical flow extraction scheme.
Fig. 7: Motion segmentation result for Stefan video. The images in the first row denote two consecutive frames from Stefan test video. The images in the second row denote the global motion estimation error and its corresponding binary mask. The images in the last row denote the continuous and the binary motion masks using the proposed algorithm.

D. Binarization at each step vs. at the end

As mentioned earlier, the goal is to solve the binary optimization problem, but to make it a tractable problem, we approximate the binary variables with continuous variables in $[0, 1]$ (called linear relaxation), and binarize them after solving the optimization problem. There are two ways to do this binarization: The first approach solves the optimization problem in Eq. (12), and binarizes the variables $w$ at the very end; The second approach binarizes the variables $w$ after each update of $w$ in algorithm 1. We have tested both these approaches for some of the test images, and provide the results in Fig 9 for different initialization. As we can see, doing the binarization at the very end works better for some images. Results presented previously in Secs. A-C are all obtained with the first approach.

E. Robustness to Initialization

In this section we present the stability of the algorithm with respect to the initialization of $w$. One way to evaluate the stability of the optimization algorithm and its convergence, is to evaluate the effect of initialization in the final results. If the final result does not depend much on the initialized values, it shows the robustness of the algorithm. To make sure the proposed algorithm is robust to the initialization, we provide the segmentation results for a test images, with 5 different initializations in Figure 10. The first one is to initialize the $w$ values with all zeros. The second one is to initialize them with the constant value of 0.5. The third one is to initialize them with Gaussian random variable with mean and variance equal to 0.5 and 0.1 respectively (and clipping the values to between 0 and 1). The fourth one is to initialize them with uniform distribution in $[0,1]$. And the last scheme is to perform least squares fitting using $P_1$ only as the basis, and consider the pixels with large fitting error as foreground. It is worth mentioning that the number of iterations in our optimization is set to 10, which is not very large to make the effect of initialization disappear. As we can see the segmentation results with different initialization schemes are roughly similar, showing the robustness of this algorithm.

F. Choice of Subspaces

As we can see from the optimization problem in Eq (12), we assume that the subspaces/dictionaries are known beforehand. It is obvious that the choice of $P_1$ and $P_2$ significantly affects the overall performance of the proposed signal decomposition framework. Choice of $P_1$ and $P_2$ largely depends on the applications.

One could choose these subspaces by the prior knowledge in the underlying applications. For example as it is shown in the experimental result section, for separation of smooth background from foreground text and graphics, DCT and
Hadamard subspaces are shown to be suitable for background and foreground components respectively.

We can also use subspace/dictionary learning algorithms to learn the subspaces for our application. There are many algorithms available for subspace/dictionary learning [35]-[39]. The ideal subspace for each component should be such that, this component can be efficiently (with small error and sparse representation) represented in that subspace, but the other component cannot be.

In the case, where it is possible to access training data which only consist of individual components, one could use the Karhunen-Loeve transform [40] or K-SVD algorithm on a large training set, to derive $P_1$ and $P_2$ separately. In the more general case, where we do not have a training set of individual signals, one could use a training set of super-imposed signals, and use an optimization framework that jointly learns two subspaces.

Through experimental study, we found out using DCT subspace for background [41], and Hadamard [42] for foreground is usually more suitable than other choices. Figure 11 shows a comparison between segmentation results using low-frequency DCT subspace for both background and foreground, and DCT subspace for background and Hadamard subspace for foreground. As we can see using Hadamard bases for foreground yields much better results.

VI. CONCLUSION

This paper looks at the signal decomposition problem under overlaid addition, where the signal values at each point comes from one and only one of the components (in contrast with the traditional signal decomposition case, which assumes a given
signal is the sum of all signal components). This problem is formulated in an optimization framework, and an algorithm based on the augmented Lagrangian method is proposed to solve it. Suitable regularization terms are added to the cost function to promote desired structure of each component. We evaluate the performance of this scheme for different applications, such as 1D signal decomposition, text extraction, and moving object detection. We also provide a comparison of this algorithm with some of the previous signal decomposition techniques on image segmentation task.

ACKNOWLEDGMENT

The authors would like to thank Ivan Selesnick, Arian Maleki, and Pablo Sprechmann for their valuable comments and feedback regarding this work. We also thank Michael Black’s group and Stephen Becker for providing us the source code for optical flow extraction, and Fast-RPCA respectively.

APPENDIX. ALTERNATING OPTIMIZATION FOR MASK EXTRACTION

In this section we provide the the optimization update for the problem in Eq (11) for the case where we have no no total variation regularization in the cost function, which is shown in Eq (23).

\[
\min_{w,\alpha_1,\alpha_2} \frac{1}{2} \| f - (1 - w) \circ P_1 \alpha_1 - w \circ P_2 \alpha_2 \|^2 + \lambda_1 \| w \|_1
\]

\[
\text{s.t. } w \in [0,1]^n, \| \alpha_1 \|_0 \leq k_1, \| \alpha_2 \|_0 \leq k_2
\]

(23)

In this case, we do not need to introduce auxiliary variables and use augmented Largangian algorithm. We can simply solve this problem with alternating optimization. The optimization with respect to \( \alpha_1 \) and \( \alpha_2 \) are simple, as it is basically a least square fitting problem. But we show the optimization with respect to \( w \) here. By using the equality \( \text{diag}(w) P_2 \alpha_2 = \text{diag}(P_2 \alpha_2)w \), we can re-write the optimization w.r.t. \( w \) as below:

\[
\min_{w} \frac{1}{2} \| f - \text{diag}(P_1 \alpha_1)(1 - w) - \text{diag}(P_2 \alpha_2)w \|^2 + \lambda_1 \| w \|_1
\]

\[
\text{s.t. } w \in [0,1]^n
\]

(24)

First note that, we can simplify the above optimization problem as below:

\[
\min_{w} \frac{1}{2} \| h - Cw \|^2 + \lambda_1 \| w \|_1
\]

\[
\text{s.t. } w \in [0,1]^n
\]

(25)

where \( C = \text{diag}(P_2 \alpha_2) - \text{diag}(P_1 \alpha_1) = \text{diag}(P_2 \alpha_2 - P_1 \alpha_1) \), and \( h = f - P_1 \alpha_1 \). We can first ignore the constraint, and then projecting the optimal solution of the cost function onto the feasible set \( (w \in [0,1]^n) \). Since \( C \) is a diagonal matrix, the cost function can be decoupled in the components of \( w \) as:

\[
\min_{w} g(w) = \frac{1}{2} \| h - Cw \|^2 + \lambda_1 \| w \|_1
\]

\[
= \sum_{i=1}^n g_i(w_i) = \sum_{i=1}^n \frac{1}{2} |h_i - C_{ii}w_i|^2 + \lambda_1 |w_i|_1
\]

(26)

where \( C_{ii} \) denotes the i-th diagonal element of \( C \). Now this problem can be easily solved with soft-thresholding as:

\[
w_i = \frac{1}{C_{ii}} \text{soft}(h_i, \lambda_1/C_{ii})
\]

(27)

Now if we denote the projection operator on \([0,1]\) by \( \Pi_{[0,1]}(w) \), then the optimization solution of \( w \) step would be:

\[
w_i^* = \Pi_{[0,1]} \left( \frac{1}{C_{ii}} \text{soft}(h_i, \lambda_1/C_{ii}) \right)
\]

(28)

This is quite interesting that the optimization w.r.t. each variable has an exact solution, and there is no nested loop involved in the proposed framework. It is worth to note that, replacing the \( |w|_1 \) regularization, with a group sparsity would also lead to a simple solution in \( w \) step.
