Abstract

Introduction: Long-term disease duration of ulcerative colitis (UC) is known to increase the risk of developing colorectal cancer in adults; however, this association has not been genetically analyzed in children with UC. Herein, we examined the expression of cancer-related genes in the colonic mucosa of pediatric UC patients and their risk of developing colorectal cancer. Methods: Microarray analysis of cancer-related gene expression was conducted on rectal mucosa biopsy specimens randomly selected from pediatric cases, including 4 active-phase UC cases, 3 remission-phase UC cases, and 3 irritable bowel syndrome control cases. The subject pool was then expanded to 10 active-phase cases, 10 remission-phase cases, and 10 controls, which were analyzed by real-time polymerase chain reaction (PCR) and immunohistochemical staining. Results: The microarray results indicated significantly higher expression levels of cancer-related genes PIM2 and SPI1 in the active group than in the remission and control groups (p < 0.05). Real-time PCR confirmed that PIM2 and SPI1 expression levels were significantly higher, whereas TP53 and APC expression levels were significantly lower, in the active-phase group than in the remission and control groups (p < 0.05). Immunohistochemical staining for PIM2, SPI1, TP53, and APC proteins supported the real-time PCR results. Conclusions: Expression levels of previously unreported cancer-related genes in adult UC patients were significantly higher in pediatric UC patients than in controls. Inflammation of the gastrointestinal mucosa increased the expression levels of cancer-related genes even in childhood-onset UC cases, suggesting that chronic inflammation from childhood may increase the risk of colorectal cancer development.

Introduction

Inflammatory bowel disease (IBD) causes chronic inflammation in the gastrointestinal tract with cycles of relapse and remission. IBD is classified into 2 main types, ulcerative colitis (UC) and Crohn’s disease, and causes symp-
Cancer-Related Genes in Pediatric Ulcerative Colitis

The number of patients with both diseases in Japan is increasing. Indeed, a national survey estimated 170,000 patients with UC and 40,000 with Crohn’s disease in Japan in 2016 [1]. The number of pediatric patients with IBD is also increasing. Patients with UC have a higher carcinogenic risk than the general population [2]; specifically, the risk of colorectal cancer increases due to long-term morbidity associated with UC [3, 4]. Thus, colorectal carcinogenesis is a serious concern for patients with long duration from UC onset. A recent study indicated that elderly onset of UC (≥60 years of age at diagnosis) increases cancer risk [5], but cancer rates are also high in patients with childhood-onset UC in Europe and the USA. Prophylactic colorectal resection was proposed to reduce colorectal cancer mortality in patients diagnosed with UC <15 years of age, as these patients demonstrated a significantly higher risk of developing colorectal cancer than those diagnosed at an older age [6]. Similarly, a 2017 cohort study demonstrated that childhood-onset IBD increased risk of future cancer [7]. However, in childhood-onset UC, lesion development is rapid, and the clinical characteristics often differ from those in adults; that is, many patients already have severe disease at diagnosis. Furthermore, genetic factors are likely involved in young-onset cases, such as for patients in whom the disease may be caused by a congenital immune abnormality. However, no pediatric studies have analyzed the non-neoplastic mucosa and selection of patients at high risk of cancer complications, as has performed for adults [8].

The aim of this study was to analyze the expression of cancer-related genes in childhood-onset UC patients and to elucidate changes in their expression to predict future carcinogenesis risk even in childhood. These findings could provide indications for colorectal resection in consideration of future colorectal cancer complications, which could be included in UC treatment guidelines, and help stratify risk classes from childhood, becoming a basis for establishing future surveillance guidelines.

Materials and Methods

Patients and Samples

Pediatric patients with UC were randomly selected from those who visited the Juntendo University Hospital Department of Pediatrics, Tokyo, Japan, from January 2011 to December 2018 with reported abdominal pain, diarrhea, and bloody stool. Ten patients with UC diagnosed in the active phase were classified into Group A, and 10 patients with a treatment history of UC in clinical remission were classified into Group B. Ten patients with all negative tests who received a diagnosis of IBS according to the Rome IV criteria [9] were classified into Group C. Individuals with a history of treatment for severe liver, heart, kidney, blood, or other systemic diseases were excluded. Gastrointestinal endoscopy was performed on all patients, and specimens of rectal mucosa were collected for histopathological examination. Samples of rectal mucosa were collected and analyzed based on previously described procedures [8, 10]. This study protocol complied with the ethical guidelines of the Declaration of Helsinki and was approved by the hospital Ethics Committee of Juntendo University Hospital (No. 18-226), and written informed consent was obtained from patients and their legal guardians. Specimens were used for microarray, real-time polymerase chain reaction (PCR), and immunohistochemical (IHC) analyses.

RNA Extraction from Mucosal Biopsy Samples

Endoscopic mucosal biopsy specimens were preserved in RNA later (Applied Biosystems, Life Technologies, Carlsbad, CA, USA) and stored at −80°C. For microarray and real-time PCR analyses, specimens were disrupted with RNasey lysis buffer and homogenized, and RNA was extracted using the RNasey Mini Kit (Qiagen, Germantown, MD, USA). RNA quantity and purity were assessed using a NanoDrop ND-1000 spectrophotometer (Thermo Fisher Scientific, Waltham, MA, USA) and the Experion RNA StdSens Analysis Kit (Bio-Rad Laboratories, Hercules, CA, USA).

Microarray Hybridization and Data Analysis

Rectal mucosa biopsy samples were randomly selected from 4 active-phase patients, 3 remission-phase patients, and 3 IBS controls, and the microarray expression profiles of cancer-related genes were compared. Relative gene expression was determined by microarray analysis using the Ambion WT Expression Kit (Applied Biosystems) and the GeneChip WT Terminal Labeling and Controls Kit (Affymetrix, Santa Clara, CA, USA), according to the manufacturers’ instructions. Specifically, total RNA was reverse-transcribed into cDNA using random primers. Next, cRNA was synthesized from cDNA by in vitro transcription. The cRNA was then used as the second cycle template for cDNA synthesis. The cDNA was fragmented, labeled, and hybridized to the GeneChip Human Gene 2.0 ST Array (Affymetrix) at 40°C for 16 h, which contained approximately 40,000 genes. The chip was washed, stained with streptavidin-phycocerythrin, and scanned using GeneChip Scanner 3000 7G (Affymetrix). Scanned images were converted to CEL files using GeneChip Command Console Software (AgGCC) (Affymetrix), and data analysis was performed using GeneSpring GX v11 software (Agilent Technologies, Santa Clara, CA, USA). Data from each chip were normalized using the RMA algorithm. Results were searched, and differentially expressed genes between Groups A, B, and C were selected. We also searched for genes that were previously reported to be specifically associated with colorectal cancer.

Real-Time PCR Analysis

Real-time PCR was performed using the cDNA synthesized from the colonic biopsy RNA preparation using the High-Capacity cDNA Reverse Transcription Kit (Applied Biosystems) with the 7,500 Fast Real-Time PCR System (Applied Biosystems). TaqMan gene expression assays targeting PIM2, SPI1, TP53, and APC (Thermo Fisher Scientific) were employed to examine gene expression levels in the rectal mucosa of patients with UC and IBS, which were compared with expression levels of differentially expressed genes identified in the microarray analysis. The expression level of each gene was normalized to that of glyceraldehyde 3-phosphate dehydrogenase (GAPDH) using the standard curve method.
IHC Analysis of PIM2, SPI1, TP53, and APC

IHC staining of mucosal epithelium tissue specimens was performed using the Benchmark GX IHC/ISH Automated Staining Instrument and Nexes IHC Automated Immunohistochemistry Staining System (both Ventana Medical Systems, Tucson, AZ, USA) according to the manufacturer’s protocols. Serial sections (3 μm thick) were prepared from formalin-fixed, paraffin-embedded rectal mucosa samples. After washing the paraffin sections with deparaffinized water, the following primary antibodies were diluted and added to the sections: PIM2 (1:100; Novus Biologicals, Centennial, CO, USA), SPI1 (1:100; Abcam, Cambridge, UK), TP53 (1:100; OriGene Technologies, Inc., Rockville, MD, USA), and APC (1:50; Abcam). Antigen activation was performed for 10 min at 121°C using 10 mM citrate buffer (pH 6.0). All heating was performed in an autoclave, and after washing, the sections were incubated with a biotin-conjugated secondary antibody. The sections were then incubated for 30 min with streptavidin (Dako, Carpinteria, CA, USA). Peroxidase activity was blocked with 3,3’-diaminobenzidine tetrahydrochloride containing 0.01% H2O2. Prior to examination by light microscopy, all sections were counterstained with hematoxylin, and normal rabbit immunoglobulin (Dako) or mouse immunoglobulin (Dako) was used as a negative control.

Statistical Analysis

Microarray data were analyzed using t tests. Mann-Whitney U tests were performed in patients’ details and real-time PCR data. A p value <0.05 was considered statistically significant. All statistical analyses were performed using EZR statistical software [11].

Results

Patient characteristics are listed in Table 1. There were no differences in mean age among the 3 groups. The male:female ratio was similar in Groups A and C, although there were more females in Group B. The Pediatric Ulcerative Colitis Activity Index (PUCAI) [12] was higher in Group A than in Group B, whereas the mean disease duration was significantly higher in Group B than in Group A. Erythrocyte sedimentation rate (ESR) and fecal occult blood (FOB) biomarkers in Group A were significantly higher than those in Group B and Group C. The average Mayo endoscopic subscore (MES) [13] was 1.5 for Group A and 0.1 for Group B, and there was significant difference between the 2 groups. But no significant difference was observed in disease activity markers between Group B and Group C. Lesions in 16/20 patients (80%) with UC involved the entire colon, and inflammation tended to be widespread, similar to the typical characteristics of childhood-onset UC.

Microarray Gene Expression Analysis

The results of gene microarray analysis are presented in Table 2. Exploration of the changes in cancer-related gene expression indicated that PIM2 and SPI1 expression levels were significantly higher in Group A than in Group

Cancer-Related Genes in Pediatric Ulcerative Colitis

Real-Time PCR Analysis

Real-time PCR results are shown in Figures 1 and 2. Expression levels of oncogenes PIM2 and SPI1 were significantly higher in Group A than in Group C (PIM2: \( p = 0.002 \), SPI1: \( p = 0.003 \)). The expression level of PIM2 decreased significantly between Group A and Group B (\( p = 0.02 \)), whereas the expression level of SPI1 did not differ between these 2 UC groups. Expression levels of tumor suppressor genes TP53 and APC were significantly lower in Group A than in Group C (TP53: \( p = 0.02 \), APC: \( p = 0.002 \)). However, the expression level of TP53 in Group B did not differ significantly from that in Group A. The expression level of APC in Group B was significantly higher than that in Group A, but did not differ significantly from that in Group C. In other words, oncogenes PIM2 and SPI1 and tumor suppressor genes APC and TP53 demonstrated opposite expression trends among the groups.

IHC Analysis

The IHC results are shown in Figures 3 and 4. Staining of target proteins by IHC revealed the same expression patterns observed by real-time PCR. Specifically, among mucosal epithelium inflammatory cells, the number of PIM2-positive cells was increased in Group A compared with that in Group C and was also increased in Group B compared with that in Group A. Fewer TP53-positive cells were observed in both Groups A and B compared to Group C. Although APC-stained cells showed a decreasing trend in Group A compared with Group C, similar findings were observed in Groups B and C.

Discussion

At present, UC-associated colitis-associated cancer is believed to be the result of inflammatory carcinogenesis in the mucous membrane [8, 14]. General colorectal cancer develops according to the adenoma-carcinoma multistage sequence [15]. However, in colitis-associated cancer, an atypical mucosa (i.e., dysplasia) develops against the background of inflammation according to the dysplasia-carcinoma sequence, which varies according to the order in which gene mutations are expressed [16]. The proposed mechanism is that mucous membranes chronically inflamed by UC accumulate genetic abnormalities due to long-term inflammation and exposure to cytokines, gradually increasing the risk factors of carcinogenesis. However, the precise mechanism of colorectal cancer development from UC remains unresolved. Gene analysis in adult UC patients and studies investigating cancer-related genes have been frequently published, identifying genes associated with carcinogenesis of adult colitis-associated cancer [8, 14–18]. However, protein expression levels of genes of interest have not been reported in children. Therefore, this study is the first to comprehensively analyze cancer-related genes in pediatric UC patients. The results of this study suggest that chronic

C (\( p < 0.05 \)). However, the expression levels of these genes between Groups B and C did not differ significantly. The expression levels of TP53 and APC, genes that are reportedly associated with colorectal cancer in adults, did not differ significantly among the 3 groups.

Cancer-Related Genes in Pediatric Ulcerative Colitis

Digestion 2022;103:150–158
DOI: 10.1159/000519559
mucosal inflammation from childhood might cause overexpression of cancer-related genes other than those previously reported in colon cancer or adult colitis-associated cancer [8, 14]. *PIM2* and *SPI1*, which have not been previously associated with carcinogenesis of colitis-associated cancer, were expressed at significantly higher levels in pediatric UC patients than in the control group, suggesting their involvement in the development of colon cancer due to inflammatory changes in the gastrointestinal mucosal epithelium.

*PIM2* encodes a serine/threonine kinase that regulates cell proliferation signaling and is abundant in hematopoietic tissues and the gastrointestinal tract. *PIM2* is highly expressed in leukemia and colorectal cancer and has been associated with other cancers [19, 20]. In addition, the *PIM2* expression level was reportedly increased in the gastric mucosa of children with *Helicobacter pylori* infection and may be involved in gastric cancer [10]. Chronic inflammatory changes in the digestive tract, especially in the mucosal epithelium, were confirmed to increase *PIM2* expression, suggesting its potential role in carcinogenesis in the digestive tract. Furthermore, *PIM2* expression was restored close to normal levels when mucosal inflammation was improved, and clinical remission

**Fig. 1.** Real-time PCR analysis of *PIM2* and *SPI1* expressions in rectal mucosal biopsy specimens. was achieved by proper treatment. These findings suggest that improving chronic inflammation of the gastrointestinal mucosa is an important factor for reducing carcinogenesis risk.

SPI1 encodes a transcription factor that activates the expression of genes involved in cell proliferation in bone marrow [21] and is reportedly a poor prognostic biomarker for childhood T-cell acute lymphoblastic leukemia [22, 23]. SPI1 is also involved in T-cell biology and is reportedly associated with regulatory T cells, UC, colorectal cancer, and colitis-associated cancer [24–26]. Therefore, SPI1 might cause colitis-associated cancer by affecting some regulatory T cells in the mucosa of the digestive tract. In addition, the results of this study demonstrated higher SPI1 expression levels in the active phase of UC when the gastrointestinal mucosa was chronically exposed to inflammatory factors, which was maintained even during the clinical remission period. In addition, IHC analysis revealed increased abundance of SPI1-positive cells among the mucosal epithelial cells, similar to PIM2-positive cells. Generally, it is hypothesized that the number of cancer cells in the epithelium increases because of chronic inflammatory changes, and they then evade selection for apoptosis and gradually become cancerous. Our findings that SPI1 expression remained unchanged throughout UC onset support the suggestion that SPI1 expression might be one of the contributors to the persistently high and increasing risk of colorectal cancer in UC patients over time.

TP53 and APC are both tumor suppressor genes associated with general colorectal cancer without UC [17]. Carcinogenesis suppression is presumed to be impaired if wild-type expression of these genes is reduced or if the gene is mutated. TP53 is often reported in inflamed regions in adult UC patients, as are APC gene mutations [14]. Overexpression of TP53 protein occurs early in UC carcinogenesis, which gradually increases by 90% in invasive cancer [18]. The cause of TP53 mutations in early-stage UC remains unclear. Analysis of existing genetic abnormalities in the non-neoplastic mucosa of adults at high risk of cancer complications indicated that the carcinogenic risk class could be predicted with 88.7–94.3% accuracy by analyzing 40 different genes [8]. In the current study, expression levels of TP53 and APC were significantly lower in the UC-active group than in the control group, suggesting that suppression of carcinogenesis was affected even in pediatric UC patients and could lead to carcinogenesis in the future. In addition, both expression and gene mutations of TP53 and APC have been reported in colitis-associated cancer [27]. Mutations in APC occur most often and are estimated to occur in most patients with general colon cancer. However, in colitis-associated cancer, as few as 16% of colon cancers harbored APC mutations, while as many as 66% harbored mutations in TP53, further emphasizing the possibility that colitic and general colon cancers develop by different mechanisms. TP53 and APC have also been shown to not only affect general colorectal cancer, but also colitis-associated cancer. Furthermore, a TP53 mutation was also detected in dysplasia, which is a precancerous lesion of colitis-associated cancer and considered already present in the early stage of carcinogenesis from UC [28, 29]. However, our study suggests that some change might occur between the onset of UC and dysplasia, which could be the initiator of carcinogenesis. These results indicate expression changes of some cancer-related genes even at initial UC onset, and that chronic inflammation from childhood might be involved in the development of colorectal cancer. Recommendations for screening and surveillance of colitis-associated cancer are provided in Europe and the USA [30–32]. Although the Japanese Society of Gastroenterology recommends endoscopy every 1–2 years for patients with colitis and UC, there is no consensus on surveillance of cancer risk in pediatric patients. Based on our findings and those of other studies, monitoring patients and analyzing changes in oncogene expression over time, including additional analysis for patients who have developed cancer, will better enable assessment of cancer risk.

This study had several limitations. Only a small number of patients from a single institution were included for analysis; therefore, the results might be affected by biases in patient backgrounds and regional differences. For this reason, this study should be expanded to include more cases across multiple facilities. In some patients, the time course after UC onset was relatively short, and analysis was performed at an early stage after mucosal inflammation occurred, which might not necessarily constitute chronic inflammatory conditions. Further, the involvement of PIM2 and SPI1 in the oncogenesis of colitis-associated cancer was not elucidated in this study. Moreover, different groups were compared and examined in this study, but analyzing cancer-related gene changes over time would necessitate regular follow-up over an extended period of time. Finally, we only considered pediatric UC patients who had not developed cancer, and neither adult UC patients nor adult patients with colitis-associated cancer were included here. Therefore, confirming whether these gene expres-

Arai/Kudo/Tokita/Kyodo/Sato/Miyata/Hosoi/Ikuse/Jimbo/Ohtsuka/Shimizu
sion changes also occur in adult UC patients or are directly involved in cancer progression requires further study. Already, we are preparing for analysis of adult patients, in collaboration with the Department of Gastroenterology in our hospital and with approval by the Ethics Committee.

Conclusion

This is the first study to identify cancer-related genes in pediatric UC patients. Furthermore, cancer risk could be stratified according to expression of these genes from initial diagnosis, and indications for preventive colorectal resection could be classified. We also believe that effective therapeutic surveillance should be established from childhood.
