Abstract

Formation and evolution of topological defects in course of non-equilibrium symmetry breaking phase transitions is of wide interest in many areas of physics, from cosmology through condensed matter to low temperature physics. Its study in strongly coupled systems, in absence of quasiparticles, is especially challenging. We investigate breaking of U(1) symmetry and the resulting spontaneous formation of vortices in a (2 + 1)-dimensional holographic superconductor employing gauge/gravity duality, a ‘first-principles’ approach to study strongly coupled systems. Magnetic fluxons with quantized fluxes are seen emerging in the post-transition superconducting phase. As expected in type II superconductors, they are trapped in the cores of the order parameter vortices. The dependence of the density of these topological defects on the quench time, the dispersion of the typical winding numbers in the superconductor, and the vortex-vortex correlations are consistent with predictions of the Kibble-Zurek mechanism.
**I. INTRODUCTION**

Critical dynamics in strongly coupled non-equilibrium phase transitions is one of the most interesting and important problems in modern physics [1]. The conventional quasiparticle approaches do not apply in this case. We study the critical dynamics of the superconducting phase transition, focusing on the formation and evolution of topological defects, by utilizing the AdS/CFT correspondence [2]. Generation of topological defects is expected in such transitions and can be used to test the Kibble-Zurek mechanism (KZM) [3, 4].

The basic idea of KZM is that, as a system approaches the critical point starting in the symmetric phase, its dynamics undergoes critical slowing down reflected in the divergence of the relaxation time. As a consequence, different domains of the system cannot communicate with each other, and select how to break the symmetry independently. The dimension of these domains is limited by the size of the sonic horizon — by how far the relevant sound can propagate in the near-critical time interval. These independent choices of the broken symmetry lead to irreconcilable differences — formation of topological defects can be expected, and has been observed. Numerical simulations [5–11] as well as experiments in liquid crystals [12–14], $^3$He superfluids [15, 16], Josephson junctions [17–20], thin-film superconductors [21–23] and quantum optics [24] have shown results consistent with KZM (for reviews, see [25, 26]).

Gauge/gravity duality has been employed to study strongly coupled systems to bypass the difficulties caused by the absence of quasiparticles [27–30], for a review see [31]. Previous studies on KZM in holographic superfluids and 1D superconducting loop can be found in [32, 33]. In these two holographic studies, scaling laws between number density of defects and the quench time were found to match KZM in slow quench regime. Other papers on holographic KZM are [34, 35].

We use the AdS/CFT correspondence to examine the U(1) gauge symmetry breaking in the (2+1)-dimensional boundary system, and study the non-equilibrium critical dynamics in a strongly coupled field theory. The spontaneous generation of magnetic fluxons (with quantized fluxes) is observed for the first time using holographic numerical simulation, Fig. 1. Spatial distributions and other characteristics of these topological defects are investigated. This includes their density as a function of the quench time, the dispersion of the typical winding numbers in the resulting superconductor, the flux distribution, and the correlation between the charges and locations of topological defects. We conclude that the resulting defects exhibit the short-range and nearest neighbor vortex-antivortex correlations consistent with the predictions from KZM.

**II. RESULTS**

As observed by Kibble [3], in the early Universe symmetry breaking phase transitions induce local choices of broken symmetry that cannot be coordinated between domains larger than the distance travelled by light since Big Bang till the phase transition. The resulting a patchwork of domains can then lead to topological defects.

In the laboratory setting speed of light is no longer relevant. However, critical slowing down that occurs in course of second order phase transitions limits the size of the domains. Equilibrium critical exponents can then predict scaling of the defect density as well as other excitations as a function of the quench time [4].
A. Magnetic fluxons from symmetry breaking

**FIG. 1: Holographic setup and birth of topological defects.** (a) Complex scalar field $\Psi$ and the U(1) gauge field $A_\mu$ are living in the bulk of Schwarzschild-AdS$_4$ spacetime. Quenching temperature across the critical point induces quantized vortices on the (2+1)-dimensional boundary, leading to the holographic KZM. (b) Configurations of the magnetic fluxons and their corresponding locations are shown at the bottom. Red arrow points at a positive magnetic fluxon with magnetic flux $\Phi \approx 1.9955\pi$. (c) Configurations of the order parameter vortices and the density plot at the bottom. Streamlines with arrows indicate the directions of phases in the complex plain of the order parameter. Locations of the cores of the vortices and the positions of the magnetic fluxons in panel (b) coincide.

Requirements of minimal free energy and periodicity of the phase $\theta$ of the complex scalar field $\Psi$ imply the quantization of the magnetic fluxes generated from U(1) symmetry breaking \[36\], i.e., $\Phi = 2\pi Z$, where $Z$ is an integer. Typical configurations of magnetic fluxons and order parameter vortices generated from U(1) symmetry breaking after quench (with quench time $\tau_Q = 1000$) are presented in Fig.1(b) and Fig.1(c), respectively. The configurations are in final equilibrium state with temperature $T_f = 0.9T_c$. The magnetic flux indicated by a red arrow in Fig.1(b) has $\Phi \approx 2\pi$, which demonstrates the quantization of magnetic flux. All ten positive magnetic fluxons shown in this plot have the average $\Phi \approx (1.9864 \pm 0.0067)\pi$; while the other ten negative
magnetic fluxons have average $\Phi \approx (-1.9834 \pm 0.0093)\pi$. Therefore, the net magnetic flux of the whole system vanishes within numerical errors, consistent with the fact that there is no external magnetic field imposed for the system. Thus, all magnetic fluxons are spontaneously generated from $U(1)$ symmetry breaking due to KZM. At the bottom of Fig. 1(c), we show the density plot of the order parameter vortices and the streamlines for the angle of the scalar field phase $\theta$. The arrows indicate the directions of the phase angles. One can read out the positive or negative vorticity of the vortices from the streamlines. Consequently, we see that the locations of positive vortices correspond to positive magnetic fluxons, and vice versa.

B. Kibble-Zurek mechanism

Near the critical point of a second order phase transition, both the relaxation time $\tau$ and the correlation length $\xi$ diverge as,

$$\tau = \tau_0 |\epsilon|^{-\nu}, \quad \xi = \xi_0 |\epsilon|^{-\nu},$$

where $\epsilon = 1 - T/T_c$ is the reduced dimensionless temperature (or, more generally, dimensionless distance from the critical point), while $\nu$ and $z$ are spatial and dynamical critical exponents. One can usually assume that $\epsilon$ traverses the critical point approximately linearly in time $t$

$$\epsilon(t) = 1 - T(t)/T_c = t/\tau_Q.$$

Above $\tau_Q$ is the quench time.

KZM recognizes that at the instant $\hat{t}$ before the critical point, when the rate of change imposed by the quench is comparable to the system’s relaxation time $\tau$, the order parameter will cease to follow or even approximate its equilibrium value. Thus, one obtains

$$\epsilon(\hat{t})/\dot{\epsilon}(\hat{t}) = \tau(\hat{t}) \Rightarrow \hat{t} = \frac{1}{\tau_0^{1/\nu z}} \frac{\nu z}{\tau Q}.$$ 

Time $-\hat{t}$ marks the beginning of the non-adiabatic evolution and $+\hat{t}$ its end. What happens inbetween is occasionally described as a “freeze-out” but a more accurate picture, especially in the cases when the order parameter is underdamped, is based on the idea of “sonic horizon” – distinct parts of the system can still evolve and influence one another, but they can coordinate their choices of broken symmetry only at distances given by how far the relevant sound (associated with the perturbations of the order parameter) can propagate during the time interval ($-\hat{t}, +\hat{t}$) \[4\].

Now, from Eq.(1) and Eq.(3), one can obtain the corresponding correlation length,

$$\hat{\xi} = \xi_0 (\tau_Q/\tau_0)^{\nu z/\nu z}.$$ 

The new, post-transition order parameter will randomly select how to break symmetry in domains that are this far apart, as they have no time to communicate with one another. This sonic horizon argument \[4\] leads to domains having the size $\sim \hat{\xi}$ – same scaling (although different pre-factors \[37\]) as these given by the “freeze-out”.

For vortices in two-dimensional space the estimated number density of point defects is:

$$n \propto \hat{\xi}^{-2} = \xi_0^{-2} (\tau_0/\tau_Q)^{2\nu z/\nu z}.$$ 

4
The same scaling laws (although, again, with somewhat different prefactors) follow from the arguments based on the “sonic horizon” paradigm \[4, 26, 37, 38\]. Equations (3), (4) and (5) can be used to test the validity of KZM in laboratory experiments and in numerical simulations.

Another important feature of KZM is the spatial distribution of the charges of topological defects. KZM predicts that the random choices of the locally broken symmetry – e.g., phase of the superfluid wavefunction – will ultimately lead to anticorrelated charges of topological defects. Therefore, one can expect that defects will exhibit short-range, nearest neighbor vortex-antivortex pairing. This is in contrast to the possibility that topological charges are distributed at random.

The scalings of the typical winding number $W$ subtended by a loop $C$ with circumference $C = 2\pi r$ can be used to distinguish between these two alternatives \[39\]. The winding number $W$ inside $C$ is $W \approx n_+ - n_-$ where $n_+$ and $n_-$ are the numbers positively and negatively charged vortices inside $C$. If vortices were distributed at random with randomly assigned topological charges, the dispersion of typical winding numbers $\sqrt{\langle W^2 \rangle}$ would be proportional to the square root of total number of defects, $n \equiv n_+ + n_-$ inside the loop. Therefore, it would scale as a square root of the area $A_C$ inside $C$, i.e., $\sqrt{\langle W^2 \rangle} \propto \sqrt{n} \propto \sqrt{A_C} \propto C$.

However, according to KZM \[39\], the broken symmetry of the local order parameter – e.g., phases of the superfluid wavefunction – rather than topological charge of defects is distributed at random. Therefore, $W$ is determined by the winding of the phase along the loop $C$. The random choices of the phase in $\hat{\xi}$-sized domains along $C$ imply that the accumulated typical winding number should be proportional to $\sqrt{C/\hat{\xi}}$ as long as $C > \hat{\xi}$, where $C/\hat{\xi}$ is the number of domains with the size given by the correlation length $\hat{\xi}$. Therefore, the dispersion of $W$ predicted by KZM should scale as,

$$\sqrt{\langle W^2 \rangle} \propto \sqrt{C/\hat{\xi}} \propto \sqrt{r/\hat{\xi}}. \tag{6}$$

Furthermore, in the range $\langle W^2 \rangle \gg 1$ the absolute value of $W$ has the same scaling limit as $\sqrt{\langle W^2 \rangle}$. More precisely, the relation is \[39\],

$$\sqrt{\pi/2} \langle |W| \rangle = \sqrt{\langle W^2 \rangle} \tag{7}$$

in which the prefactor $\sqrt{\pi/2}$ comes from the Gaussian approximation to the distribution of $W$.

The above scalings need to be adjusted if the magnitude of $W$ is smaller than 1. This happens as the radius $r$ of the contour is smaller than the correlation length $r < \hat{\xi}$. In this case $W$ is proportional to the probability of finding one vortex inside $C$. Thus, $\langle |W| \rangle \approx p_+ + p_-$, where $p_+/-$ is the probability to find a positive/negative vortex. In this case $W$ only has three possible values $+1, 0$ and $-1$, thus we can deduce $\langle |W| \rangle = \langle W^2 \rangle$. Therefore, in the limit of $\langle |W| \rangle \ll 1$ we arrive at

$$\langle W^2 \rangle \approx \langle |W| \rangle \approx p_{|W|=\pm 1} \propto A_C/\hat{\xi}^2 \propto \left( r/\hat{\xi} \right)^2. \tag{8}$$

in which $A_C$ is the area surrounded by the contour $C$.

### C. Dynamics of symmetry breaking and nascent topological defects

Growth of the average absolute value of order parameter $\langle |O(t)| \rangle$ from $t = 0$ ($T = T_c$) to the final equilibrium state is seen in Fig.2(a). The instantaneous dynamical values of $\langle |O(t)| \rangle$
FIG. 2: Time evolution of the order parameter and the birth of topological defects. (a) The average absolute value of the order parameter $\langle |O(t)| \rangle$ during quenches with $\tau_Q = 100, 190, 600$ and $900$. Quenches end at final temperature $T_f = 0.64 T_c$. The black solid line is the instantaneous equilibrium value of the average condensate. Explicit examples of order parameter and magnetic field for $\tau_Q = 190$ (thick blue) are shown in the panels (b)-(f). (b) & (c) Snapshots of the cross sections of condensate and magnetic fields for a single vortex at four specific times with $\tau_Q = 190$. Their locations are indicated by the white and black arrows respectively in the subsequent panels (d)-(f). Blue curves are the profiles of the order parameter while red curves are the magnetic fields. (d), (e) & (f) Density plots of the order parameter $\langle |O(x,y)| \rangle$, phases of the order parameter $\theta(x,y)$ and the corresponding magnetic field $B(x,y)$ at four specific times with $\tau_Q = 190$, respectively.

remain negligible, i.e. close to what is was in the symmetric vacuum, and, hence, lags behind the instantaneous equilibrium values. For instance for quench with $\tau_Q = 190$, its instantaneous value remains negligible until the lag time $t_L/\tau_Q \sim 0.263$, and then begins to grow rapidly reaching the approximate equilibrium value at $t/\tau_Q \sim 0.368$. This behavior, with $t_L$ larger than but proportional to $\hat{t}$, is predicted by KZM, and was reported in the past [10, 33].

In Fig.2(b) and Fig.2(c), we track emergence of two vortices for $\tau_Q = 190$ at positions $(x,y) \approx (33, 45)$ and $(x,y) \approx (20, 20)$. We only show their cross sections along the $x$-direction in the figure. At time $t/\tau_Q = 0.315$ and $t/\tau_Q = 0.342$ there are no well-defined vortices as the order parameter is only beginning to grow. Well-defined vortices can be found in the final equilibrium state, for example at $t/\tau_Q = 0.421$ in Fig.2(d) and Fig.2(f).

The top row ($t/\tau_Q = 0.421$) in Fig.2(b) and Fig.2(c) demonstrates that the location of the minima of the order parameter coincide with the maxima of the magnetic field. Widths of the flux lines $\lambda_v$ and of the order parameter defects $d_v$ can be fitted by $B(r) \sim e^{-r/\lambda_v}$ and $\langle |O(r)| \rangle \sim \tanh(r/(\sqrt{2}d_v))$ [36]. From Fig.2(b) and Fig.2(c), we estimate $\lambda_v \approx 1.15$ and $d_v \approx 0.50$, respectively.
respectively. Thus, the Ginzburg-Landau parameter is \( \kappa = \lambda_v/d_v \approx 2.30 > 1/\sqrt{2} \), which belongs to type II superconductors \[36\].

Fig.2(d) and Fig.2(f) show the density plots of the order parameter \( \langle |O(x, y)| \rangle \) and the corresponding magnetic fields \( B(x, y) \). At final equilibrium time \( t/\tau_Q = 0.421 \), positions of the vortices (see the white and black arrows) correspond to the singular points in the density plots of order parameter phases \( \theta(x, y) \) in Fig.2(e).

D. Number density of topological defects and “freeze-out” time

![Graphs showing universal scalings of vortex number density and lag time versus quench time.](image)

**FIG. 3:** Universal scalings of vortex number density and lag time versus quench time. (a) Relation between vortex number density \( n \) and quench time \( \tau_Q \). Solid diamonds are numerical data while blue and red lines are from the best fit. Error bars denote the standard deviations. Scalings in slow quench (large \( \tau_Q \)) satisfy KZM prediction, \( n \propto \xi^{-2} = \xi_0^{-2} (\tau_0/\tau_Q)^{-7/2} \), very well. However, vortex number in fast quenches (small \( \tau_Q \)) is almost constant, independent of \( \tau_Q \). These quenches are essentially “impulse” – they start within the impulse interval \((-\hat{t}, +\hat{t})\). (b) Relations between the lag time \( t_L \) and \( \tau_Q \). Circles are the numerical data and the error bars are small compared to the size of circles. Red fitted line shows a good agreement with the KZM prediction, \( t_L \simeq \tau_Q^{7/2} \sim \hat{t} \) in the slow quench regime.

We count the vortex number density \( n \) as the average order parameter saturates to its equilibrium value. Scalings between \( n \) and \( \tau_Q \) are exhibited in Fig.3(a), with the final equilibrium temperature \( T_f = 0.64T_c \) and the size of the boundary \((x, y) = (100, 100)\). In the slow quench regime (large \( \tau_Q \)), the scaling relation is fitted as \( n \approx (836.0430 \pm 1.1844) \times \tau_Q^{-0.5126 \pm 0.0230} \), where the uncertainties give standard deviations. The quasi-normal modes (QNMs) analysis in the Appendix indicates a mean-field theory with \( \nu \approx 1/2 \) and \( z \approx 2 \). Thus, the exponent in the scaling between \( n \sim \tau_Q \) in Eq.(5) is roughly \(-1/2\), which is in good agreement with the above numerical results. By contrast, in the fast quench regime (small \( \tau_Q \) which is beyond the scope of KZM) the vortex number is approximately constant. This is consistent with the previous results \[25, 32, 33\].

The time \( \hat{t} \sim \sqrt{\tau_Q} \) in the symmetry breaking phase is the instant that the system leaves the phase of the quench when the dynamics of the systems cannot keep up with the changes imposed by the quench and enters the adiabatic region \[26\]. Following \[10, 33\] we define the lag time \( t_L \) as the time when the order parameter begins to grow rapidly. Lag time \( t_L \) reflects the “freeze-out” time \( \hat{t} \) \[10, 33\]. Scalings between \( t_L \) and \( \tau_Q \) are shown in Fig.3(b). The best fit in the slow quench...
regime (red line) is $t_L \approx (4.3345 \pm 0.0205) \times 0.4860^{+0.0007}$, in which the exponent matches KZ relation when we take $\nu = 1/2$ and $z = 2$ in Eq.(5).

E. Typical winding number $W$

The winding number $W$ is phase accumulated along the contour $C$. In the broken symmetry phase it is dominated by the net number of topological defects inside $C$. According to KZM, random choices of the phase of the order parameter determine the distribution of the topological defects. As a consequence, defect charges are not distributed randomly, but, rather, anticorrelated. This leads to predictions about the distribution of winding numbers as a function of the circumference of $C$.

![Fig. 4: Universal scalings of typical winding number $W$. (a) Typical winding number $W$ as a function of the size $r$ of the contour $C$ in which the defects are trapped. (b) Scalings between $W$ and average total number of defects $\langle n \rangle$ trapped inside contour $C$. In panels (a) and (b) the data points were obtained by averaging 200000 runs for parameters $\tau_Q = 30$ and $T_f = 0.64 T_c$. Dots and open circles are the numerical data while the solid and dashed black lines are the fittings of the data in the small and large $W$ limits, respectively.](image)

Fig.4(a) shows the relation between three functions of $W$ to the radius $r$ of the contour $C$ (with circumference $C \propto r$), inside which vortices are trapped. As $r$ is large (or $C > \hat{\xi}$), the dispersion of $W$ is proportional to the square root of $r$ as shown in Eq.(6). This scaling is reflected in our holographic results in Fig.4(a) with $\ln(\langle W^2 \rangle) \approx 1/2 \ln(r) - 1.31$. From Gaussian approximation to the distribution of $W$, one can deduce the relation $\sqrt{\pi/2}/\langle |W| \rangle = \sqrt{\langle W^2 \rangle}$ when $W$ is large, as is indicated in Eq.(7). This relation is also verified in Fig.4(a) with the ratio $\sqrt{\langle W^2 \rangle}/\langle |W| \rangle \approx e^{-1.31}/e^{-1.59} \approx 1.3321$ or using Fig.4(b) where $\sqrt{\langle W^2 \rangle}/\langle |W| \rangle \approx e^{-0.35}/e^{-0.62} \approx 1.3099$, compared to the theoretical value $\sqrt{\pi/2} \approx 1.2533$. In the opposite limit $|W| \ll 1$, Eq.(8) is verified as well using holography as we examine the scalings of $\langle W^2 \rangle$ and $\langle |W| \rangle$ in Fig.4(a) that $\ln(\langle W^2 \rangle) \approx \ln(\langle |W| \rangle) \approx 2 \ln(r) - 3.6$.

Fig.4(b) exhibits the relations between $W$ and the average total vortex number $\langle n \rangle$ inside the contour $C$. Because of $\langle n \rangle \sim A_C/\hat{\xi}^2 \propto r^2/\hat{\xi}^2$, the doublings of powers for scalings $W \sim \langle n \rangle$ and $W \sim r$ are explicitly shown by comparing Fig.4(b) and Fig.4(a). In the limit $r < \hat{\xi}$, it is usually only possible to find one vortex (either positive or negative) inside $C$, thus $\langle |W| \rangle \approx \langle W^2 \rangle \approx \langle n \rangle$ inside a small $C$. This is demonstrated as well – $\ln(\langle |W| \rangle) \approx \ln(\langle W^2 \rangle) \approx \ln(\langle n \rangle)$ in Fig.4(b) when $\langle n \rangle$ is small.
Therefore, the universal scalings of typical winding number $W$ in our holographic study are consistent with predictions from KZM [14, 39, 40].

**F. Vortex-vortex correlation function with polarity**

Correlation length $\hat{\xi}$ can be estimated from the above $W$. We see that, $\langle |W| \rangle = \langle W^2 \rangle$ as $r < \hat{\xi}$, however, this equality is violated as $r \gg \hat{\xi}$. Fig.4(a) shows that $\langle |W| \rangle$ departs from $\langle W^2 \rangle$ at around $1 < \ln(r) < 2$, thus we can estimate $2.7 < \hat{\xi} < 7.3$.

**FIG. 5: Net vortex number $n_c(r)$ and vortex-vortex correlation function $G(r)$.** (a) Profile of net vortex number $n_c(r)$. It decreases from 1 at $r = 0$ to 0 at large $r$, indicating vortex-antivortex correlations. Error bars stand for the standard deviations. (b) Profile of vortex-vortex correlation function $G(r)$. Minimum of the fitting curve indicates the correlation length as $\hat{\xi} \approx 3.7712$. Parameters $\tau_Q$ and $T_f$ are the same as FIG.4.

Following [22, 23], one can evaluate $\hat{\xi}$ from the vortex-vortex correlation function $G(r)$ with vortex polarities as well. $G(r)$ is defined as $G(r) \equiv \langle n(r)n(0) \rangle$, with $n(r) = +1/-1$ at the location of a positive/negative vortex, and 0 elsewhere. In practice, $G(r)$ can be evaluated by summing over all charges of vortices (with ± polarities) sitting at the circumference a contour $C$, whose center is at a positive vortex. Meanwhile, one can also define the net vortex number $n_c(r)$ by summing over vortex charges inside the above contour$^1$. Fig.5(a) shows that $n_c = 1$ at $r = 0$, which is obvious from its definition. Away from $r = 0$, $n_c$ decreases to zero, which demonstrates the short-range vortex-antivortex correlations. From the definition of $G(r)$, one can set $G(0) = 0$. Negative minimum of $G(r)$ in Fig.5(b) also reflects the short-range, nearest neighbour vortex-antivortex correlations between vortices, and the position of the minimum is $\hat{\xi}$. Fitting $G(r) \approx ar^2 \times e^{-br^2}$ to the theory [11,12], we get $a \approx -0.0412$ and $b \approx 0.0703$. Therefore, the correlation length can be estimated as $\xi \approx 1/\sqrt{b} \approx 3.7$, which lies in the range $2.7 < \xi < 7.3$ of our previous estimate.

$^1$ Please note the different definitions of $n_c$ and the aforementioned typical winding number $W$. $W$ is defined as the net vortex number inside a contour whose center can be anywhere; $n_c$ is defined inside a contour whose center is only at a positive vortex.
There is another length scale – mean vortex separation \( r_{av} = \sqrt{A/\langle n \rangle} \), in which \( A \) is the area of the system [22]. Thus, \( r_{av} \approx 12.9099 \) as \( \tau_Q = 30 \) from Fig.3(a) (with \( A = 100 \times 100, \langle n \rangle \approx 60 \)). Consequently, \( \xi \approx 0.2921r_{av} \) which is comparable to the experimental results \( \hat{\xi} \approx 0.35r_{av} \) in [22], where the authors studied the distributions of the magnetic flux quanta from KZM in a 2D superconducting film.

### III. CONCLUSIONS

Taking advantage of the AdS/CFT correspondence we have simulated quench-induced symmetry breaking in the transition from the normal to superconducting phase of the strongly coupled holographic field theory. We have observed formation of topological defects – fluxons with quantized fluxes trapped within the vortices, with properties consistent with type II superconductor. Their densities accord with the predictions of KZM, as does their distribution. In particular, they are anticorrelated. This is related to the distribution of the winding numbers of the phase of the condensate. They provide evidence that it is the condensate phase (i.e., post-transition choice of the broken symmetry) that is random, which in turn results in the anticorrelation of the topological charges. We have also observed that the lag time – the instant at which the order parameter begins to grow rapidly – scales as the freezeout time \( \hat{t} \), central to KZM.

Methods

**Holographic Setup:** In the probe limit, we adopt the black brane background as

\[
    ds^2 = \frac{L^2}{z^2}(-f(z)dt^2 - 2dtdz + dx^2 + dy^2),
\]

where \( f = 1 - (z/z_h)^3 \). The location of horizon is at \( z_h \) while \( z = 0 \) is the boundary where the field theory lives. The Hawking temperature of the black brane is \( T = 3/(4\pi z_h) \) which also corresponds to the temperature of the dual field theory. In the numerics we have scaled \( z_h = 1 \). We take the commonly used Einstein-Maxwell-complex scalar model in a holographic superconductor [43],

\[
    \mathcal{L} = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu} - |D\Psi|^2 - m^2|\Psi|^2.
\]

where \( D = \nabla - iA \). (Throughout this paper, we work in the units with \( e = c = h = k_B = 1 \).) The ansatz we take is \( \Psi = \Psi(t, z, x, y), A_t = A_t(t, z, x, y), A_x = A_x(t, z, x, y), A_y = A_y(t, z, x, y) \) and \( A_z = 0 \). Then the equations of motion (EoM) read,

\[
    D_\mu D^\mu \Psi - m^2 \Psi = 0, \quad \nabla_\mu F^{\mu\nu} = i(\Psi^* D^\nu \Psi - \Psi (D^\nu \Psi)^*),
\]

The asymptotic expansions of fields near the boundary \( z \to 0 \) are (we have set \( m^2 = -2/L^2 \))

\[
    A_\mu \sim a_\mu + b_\mu z + \ldots, \quad \Psi = z L (\Psi_0 + \Psi_1 z + \ldots)
\]

In the numerics we have scaled \( L = 1 \). From AdS/CFT correspondence, \( a_t, a_i \ (i = x, y) \) and \( \Psi_0 \) are interpreted as the chemical potential, gauge field velocity and source of scalar operators on the boundary, respectively. Their corresponding conjugate variables can be achieved by varying
the renormalized on-shell action $S_{\text{ren}}$, with respect to these source terms. From holographic renormalization \[44\], we can add the counter terms of the scalar fields $S_{\text{c.t.}} = \int d^3x \sqrt{-\gamma} \Psi^a \Psi^a$ into the divergent on-shell action, where $\gamma$ is the determinant of the reduced metric on the $z \to 0$ boundary. In order to get the dynamical gauge fields in the boundary, we impose the Neumann boundary conditions for the gauge fields as $z \to 0 \[45, 46\]$. Thus, the surface term $S_{\text{surf}} = \int d^3x \sqrt{-\gamma} n^\mu F_{\mu\nu} A^\nu$ near the boundary should be added as well in order to have a well-defined variation, where $n^\mu$ is the normal vector perpendicular to the boundary. Hence, we obtain the finite renormalized on-shell action $S_{\text{ren}}$. Therefore, the expectation value of the order parameter, $\langle O \rangle = \Psi_1$, can be obtained by varying $S_{\text{ren}}$ with respect to $\Psi_0$. Expanding the $z$-component of Maxwell equations near boundary, we get $\partial_t b_t + \partial_i J^i = 0$, which is exactly a conservation equation of the charge density and current on the boundary, since from the variation of $S_{\text{ren}}$, one can easily deduce that $b_t = -\rho$ with $\rho$ the charge density and $J^i = -b_i - (\partial_i a_t - \partial_t a_i)$ which is the $i$-direction current respectively.

On the boundary, we set $\Psi_0 = 0$ in order to have spontaneously broken symmetry of the order parameter. The Neumann boundary conditions for the gauge fields can be imposed from the above conservation equations. Therefore, dynamical gauge fields on the boundary can be computed and lead to the spontaneous formation of magnetic vortices. Moreover, we impose the periodic boundary conditions for all the fields on the spatial boundary along $(x,y)$-directions. Near the horizon we set $A_t(z_h) = 0$ and the regular finite boundary conditions for other fields.

From the dimension analysis, we know that the temperature of the black hole $T$ has mass dimension one, while the mass dimension of the charge density $\rho$ has mass dimension two. Therefore, $T/\sqrt{\rho}$ is dimensionless. From holographic superconductor \[43\], decreasing the temperature is equivalent to increasing the charge density. Therefore, in order to linearize the temperature near the critical point like Eq.(2), we can actually quench the charge density $\rho$ as $\rho(t) = \rho_c (1 - t/\tau Q)^{-2}$ with $\rho_c \approx 4.06$.

**Numerical Schemes:** We thermalize the system thoroughly before quench in order to make an equilibrium initial state. In order to thermalize the system initially, different from putting the seeds on the boundary in \[32, 33\], we put the random seeds of the fields in the bulk by satisfying the statistical distributions $\langle s(t, x_i) \rangle = 0$ and $\langle s(t, x_i) s(t', x_j) \rangle = h \delta(t - t') \delta(x_i - x_j)$, with the amplitude $h = 10^{-3}$. System evolves by using the fourth order Runge-Kutta method with time step $\Delta t = 0.025$. In the radial direction $z$, we use the Chebyshev pseudo-spectral method with 21 grids. Since in the $(x,y)$-directions, all the fields are periodic, we use the Fourier decomposition along $(x,y)$-directions. Filtering of the high momentum modes are implemented following the “2/3’s rule” that the uppermost one third Fourier modes are removed \[47\].

**FIG. 6:** Temperature dependence of correlation length and relaxation time in the normal and superconducting state from QNMs. (a) The dimensionless correlation length $\xi T_c$ vs. the reduced temperature $\epsilon = 1 - T/T_c$. The red line and triangles are for the superconducting phase, while the blue ones are for the normal state. The critical exponents are close to $-1/2$, which indicates a mean field theory; (b) The dimensionless relaxation time $\tau T_c$ as functions of $\epsilon$. The red line and triangles are for the superconducting phase, while the blue ones are for the normal state. The critical exponents are close to $-1$, which is consistent with the mean field theory.

From holography, QNMs correspond to the poles of the correlation functions \[48\]. We can read off the correlation length $\xi$ from the correlation function as \[49\]

$$\langle O(\omega, k)O^\dagger(-\omega, -k) \rangle \sim \frac{1}{i \tilde{c} \omega + k^2 + 1/\xi^2}.$$  \hspace{1cm} (A.1)

where $k$ and $\omega$ are the momentum and frequency of the modes of perturbations respectively, and $\tilde{c}$ is a parameter. By linearly perturb the equations of motions in Schwarzschild-AdS metric, we are able to calculate the QNMs of the scalar fields.

In the normal state, $A_t$ is the background gauge field, while $\psi$ is the first order perturbations of the scalar field $\Phi$ as $\delta \Phi = \psi(z) \exp(-i \omega t + ikx)$ and $\psi$ is real (Note that we have scaled $\Phi = \Psi/z$). The only one decoupled EoM is

$$\psi'' + \frac{f'}{f} \psi' + \left(\frac{A_t + \omega}{f^2} + \frac{zf' - k^2 z^2 + 2}{z^2 f} - \frac{2}{z^2}\right) \psi = 0$$ \hspace{1cm} (A.2)

In the superconducting state with $\Psi \neq 0$, one needs to construct gauge-invariant perturbations since there are mixed perturbations in this case. The infinitesimal gauge transformations are \[50\]

$$\{\delta a_t, \delta a_x, \delta a_z\} = \{-i \omega \lambda, ik \lambda, \lambda'(z)\},$$  \hspace{1cm} (A.3)

$$\{\delta \sigma, \delta \eta\} = \{0, \lambda \Phi\}. \hspace{1cm} (A.4)$$

in which $\sigma$ and $\eta$ are respectively the real and imaginary parts of perturbations of the scalar field, while $a_i(i = t, x, z)$ are the perturbations of the corresponding gauge fields. Thus, the independent...
gauge-invariant quantities can be built as
\[
\Phi_1 = \sigma, \quad \Phi_2 = i\omega\eta + \Phi_{a_t}, \quad \Phi_3 = -ik\eta + \Phi_{a_x}.
\]

For \( k = 0 \), the equations for the gauge-invariant quantities are
\[
\begin{align*}
\Phi_1 \left( \frac{A^2 + \omega^2}{f^2} + \frac{f'}{zf} + 2 \frac{2}{z^2 f} - \frac{2}{z^2} \Phi_2 + \frac{f'}{f} \Phi_1' + \Phi_1'' = 0, \quad (A.6) \\
\Phi_2 \left( \frac{A^2 + \omega^2}{f^2} + \frac{zf' - 2z^2\psi_0^2 + 2}{z^2 f} - \frac{2\psi_0'}{(\psi_0 f' + 2f \psi_0')} - \frac{2}{z^2} \right) + \frac{2A\Phi_1 (\omega^2 - 2f \psi_0^2)}{f^2} \Phi_1 = 0
\end{align*}
\]

in which the equations of \( \Phi_3 \) is decoupled.

For \( \omega = 0 \), the equations for gauge-invariant perturbations become
\[
\begin{align*}
\Phi_1 \left( \frac{A^2 + \omega^2}{f^2} + \frac{zf' - k z^2 - 2f + 2}{z^2 f} + 2 \left( \frac{\Phi'}{\Phi} \right) + \frac{f'\Phi'}{f\Phi} - \frac{2\Phi^2}{f} \right) + \frac{2A\Phi_1 (\omega^2 - 2f \psi_0^2)}{f^2} \Phi_1 = 0 \quad (A.8) \\
\Phi_2 \left( \frac{A^2 + \omega^2}{f^2} + \frac{zf' - k z^2 - 2f + 2}{z^2 f} + 2 \left( \frac{\Phi'}{\Phi} \right) + \frac{f'\Phi'}{f\Phi} - \frac{2\Phi^2}{f} \right) - \frac{4A\Phi_1 (\omega^2 - 2f \psi_0^2)}{f^2} \Phi_1 - \frac{2\Phi'}{\Phi} \Phi_2 + \Phi_2'' = 0 \quad (A.9)
\end{align*}
\]
in which \( \Phi_3 \) is also decoupled.

After solving the EoMs (A.8) and (A.9) one can get a series QNMs of \( k \). The correlation length \( \xi = 1/|\text{Im}(k^*)| \) where \( k^* \) is the lowest mode whose imaginary part is closest to the real axis. In Fig.6(a) we show the correlation length to the temperature both in normal state and superconducting state. We can see explicitly that \( \xi \propto |1 - T/T_c|^{1/2} \) in both phases, which indicates that \( \nu = 1/2 \) and consistent with mean field theory. The prefactors for the normal state is \( \xi_0^\sigma \approx 0.5767/T_c \approx 4.8708 \) while the one in the superconducting state is \( \xi_0^\sigma \approx 0.6195/T_c \approx 5.2323 \).

Thus in the holographic model \( \xi_0^\sigma < \xi_0^\omega \), which indicates a non-Ginzburg-Landau model.

The relaxation time \( \tau \) can be obtained similarly. By solving the EoMs (A.6) and (A.7), one can get a series modes of \( \omega \). Then \( \tau = 1/|\text{Im}(\omega^*)| \) where \( \omega^* \) is the lowest mode in those QNMs. We can see explicitly from Fig.6(b) that \( \tau \propto |1 - T/T_c|^{-1} \) for both normal and superconducting phases, which indicates that \( z = 2 \) and consistent with the mean field theory. The prefactors in the normal state is \( \tau_0^\sigma \approx 1.662/T_c \approx 14.0372 \) while the one in the superconducting state is \( \tau_0^\omega \approx 0.9574/T_c \approx 8.0862 \). The two prefactors \( \tau_0^\sigma \) and \( \tau_0^\omega \) have large discrepancy compared to Ginzburg-Landau model, because we get them by integrating the fields in the whole bulk, different from direct calculations of them in the boundary like in Ginzburg-Landau theory. It also implies that although the boundary is like a mean field theory, they are not Ginzburg-Landau type.
