Abstract

Background Some, but not all, epidemiologic evidence supports a role for cholesterol, the precursor for steroid hormone synthesis, in prostate cancer. Using a PTEN-null transgenic mouse model of prostate cancer, we tested the effect of modifying serum cholesterol levels on prostate tumor development and growth. We hypothesized that serum cholesterol reduction would lower tumor androgens and slow prostate cancer growth.

Methods PTENloxP/loxP-Cre+ mice consuming ad libitum high fat, high cholesterol diets (40% fat, 1.25% cholesterol) were randomized after weaning to receive the cholesterol uptake inhibitor, ezetimibe (30 mg/kg/day), or no intervention, and sacrificed at 2, 3, or 4 months of age. Serum cholesterol and testosterone were measured by ELISA and intraprostatic androgens by mass spectrometry. Prostate histology was graded, and proliferation and apoptosis in tumor epithelium and stroma was assessed by Ki67 and TUNEL, respectively.

Results Ezetimibe-treated mice had lower serum cholesterol at 4 months (p = 0.031). Serum cholesterol was positively correlated with prostate weight (p = 0.033) and tumor epithelial proliferation (p = 0.069), and negatively correlated with tumor epithelial apoptosis (p = 0.004). Serum cholesterol was unrelated to body weight (p = 0.195). Tumor stromal cell proliferation was reduced in the ezetimibe group (p = 0.010). Increased serum cholesterol at 4 months was associated with elevated intraprostatic DHEA, testosterone, and androstenedione (p = 0.043, p = 0.074, p = 0.031, respectively). However, cholesterol reduction did not significantly affect adenocarcinoma development at 2, 3, or 4 months of age (0, 78, and 100% in ezetimibe-treated vs. 0, 80, and 100% in mice not receiving ezetimibe).

Conclusions Though serum cholesterol reduction did not significantly affect the rate of adenocarcinoma development in the PTEN-null transgenic mouse model of prostate cancer, it lowered intraprostatic androgens and slowed tumor growth. These findings support a role for serum cholesterol in promoting prostate cancer growth, potentially via enhanced tumor androgen signaling, and may provide new insight into cholesterol-lowering interventions for prostate cancer treatment.

Introduction

Obesity is associated with increased risk of aggressive prostate cancer and elevated prostate cancer-specific mortality [1]. Currently, it is estimated that one in five US adults have uncontrolled hypercholesterolemia, a metabolic disorder associated with obesity [2]. While some epidemiologic evidence supports an association between hypercholesterolemia and increased incidence of aggressive prostate cancer [3–6], a recent meta-analysis found no significant association between serum cholesterol and either overall or high-grade disease [7]. Several studies reported positive associations between hypercholesterolemia and increased risk of prostate cancer recurrence [8, 9] and mortality [10], yet others found no associations or even inverse relationships between them [11, 12]. Statins, a group of widely prescribed cholesterol-lowering drugs, are associated with lower risk of aggressive prostate cancer [13], decreased prostate cancer recurrence [14], and reduced mortality [15]. However, it is not clear whether this effect is
due to direct effects of the statin itself or indirect effects mediated via cholesterol-lowering [16]. As such, the true biological potential of targeting serum cholesterol to slow prostate cancer growth and progression is promising, but unclear.

Cholesterol is the precursor for de novo steroidogenesis, which generates androgens crucial for prostate cancer growth [17]. Indeed, serum cholesterol reduction has been demonstrated to lower intratumoral androgen levels and slow tumor growth in a xenograft mouse model of human prostate cancer [20]. However, the effect of cholesterol reduction on prostate cancer progression has never been tested in a transgenic model, which enables assessment of tumor progression within the native prostate micro-environment. The objective of this study was to determine the effect of modifying serum cholesterol levels in tumor development and growth in an obese transgenic mouse model of prostate cancer. Given that PTEN is among the most frequently mutated/deleted genes in human prostate cancer [20], we selected the PTEN-null mouse model for this study. We hypothesized that reduction of serum cholesterol levels would lower tumor androgens and slow tumor growth.

Materials and methods

Animal study design

All animal protocols were approved by Duke University Institutional Animal Care and Use Committee. Prostate-specific homozgyous deletion of PTEN was achieved by crossing PTENlox/lox mice with mice of the ARR2Probasin-cre transgenic line PB-Cre4, where Cre recombinase is under the control of a modified rat prostate-specific probasin promoter, as previously reported [20]. Tumor progression is well-characterized in this mouse model, with development of prostatic hyperplasia by 4 weeks of age, mouse prostate intraepithelial neoplasia (mPIN) by 6 weeks of age, and invasive prostate adenocarcinoma by 9 weeks of age [20]. Following crossing PTEN mice. Seminal vesicles, bladder, and fat were removed, and the prostate was weighed and bisected along the sagittal plane. One half of the prostate was flash frozen in liquid nitrogen and stored at −80 °C, while the other was fixed in 10% formalin for 48 h and then paraffin embedded. The formalin-fixed prostate was oriented within the paraffin block to ensure representation of all prostate lobes (i.e., dorsal, ventral, and anterior) on the resulting slides.

Histologic analyses

Formalin-fixed paraffin-embedded prostate tissue was cut to generate three 4 µm sections, each separated by 50 µm, and stained with hematoxylin and eosin (H&E) for histopathologic evaluation. Slides were scanned using an Aperio ScanScope, and grading of H&Es was conducted by a single investigator (EHA) blinded to dietary group, under the guidance of a board-certified pathologist (GVT). All prostate lobes were graded across all three sections, and lesions (mPIN, invasive and intracystic adenocarcinoma) were noted as present vs. absent. Intracystic lesions were found only in the anterior lobe, while mPIN and invasive adenocarcinoma were found in all lobes.

Serial 4 µm sections were cut and stained with antibodies against Ki67 (Thermo Scientific, Rockford, IL) and TUNEL (ApopTag® Plus Peroxidase In Situ Apoptosis Kit; Millipore Inc., Billerica, MA) to assess proliferation and apoptosis, respectively, in regions of invasive adenocarcinoma across all prostate lobes. These analyses were restricted to mice 4 months of age as there was a relatively large tumor area available for assessment at this time point. Ki67 and TUNEL H score was quantified within epithelium and stroma separately using a digital pathology nuclear algorithm (Definiens Tissue Studio®) at the Translational Pathology Core, University of North Carolina at Chapel Hill. In order to assess these markers in invasive adenocarcinoma regions only, areas of normal prostate tissue were manually excluded from analysis, and areas of necrosis and cellular debris (including intracystic lesions, where present)
were excluded using the digital algorithm. As such, in mice with intracystic lesions, invasive adenocarcinoma in the area surrounding the intracystic lesion in the anterior lobe, along with invasive adenocarcinoma in ventral and dorsal lobes, was analyzed for Ki67 and TUNEL staining.

**Serum and prostate analyses**

All serum parameters were measured at 4 months of age. To assess liver health, we measured serum levels of total bilirubin, alanine transaminase (ALT), and aspartate transaminase (AST) using ELISA (Sigma Aldrich, St. Louis, MO). Serum cholesterol levels were measured using the Infinity Cholesterol Liquid Stable Reagent (Thermo Electron Corp., Waltham, MA), and serum testosterone levels were measured by ELISA (R&D systems, Minneapolis, MN). Androgen concentrations were measured in a flash frozen prostate tissue from 4-month-old mice using mass spectrometry, as previously described [21].

**Statistical analyses**

Differences in body and prostate weights, serum cholesterol levels, and tumor proliferative and apoptotic indexes between dietary groups were examined using Student’s t-tests, ensuring that variance was similar between groups being compared. Linear regression was used to examine the relationship between serum cholesterol levels and body and prostate weight, tumor proliferative and apoptotic indexes, and serum and prostate androgen levels. Statistical analysis was carried out using STATA 13.0 (Stata, Corp., College Station, TX, USA). Statistical significance was two-sided with \( p < 0.05 \).

**Results**

**Effect of serum cholesterol reduction on caloric intake and body weight**

Mean (SD) age at randomization was 31 (6) days for the HFHC group and 33 (10) days for the ezetimibe group (\( p = 0.494 \)). Caloric intake did not differ between the dietary groups (Fig. 1a), and there were no differences in body weights between the dietary groups at randomization (HFHC vs. ezetimibe; 17.3 g vs. 17.6 g, \( p = 0.800 \)) or at 4 month sacrifice (HFHC; 36.6 g vs. ezetimibe; 36.2 g, \( p = 0.767 \); Fig. 1b, c). Mice in the ezetimibe group consumed an average of 15.2 kcal per day, corresponding to an average ezetimibe dose of 26.2 mg/kg/day. Inhibition of cholesterol uptake with ezetimibe resulted in significantly reduced serum cholesterol levels by 4-months of age (ezetimibe vs. HFHC; 161 mg/dl vs. 201 mg/dl, respectively; \( p = 0.031 \); Fig. 1c). Serum cholesterol level was not significantly correlated with body weight at sacrifice (Fig. 1d). There were no differences between the dietary groups with respect to liver and spleen size (all \( p > 0.1 \); Supplementary Figure S1), or liver function (all \( p > 0.1 \); Supplementary Figure S2).

**Effect of serum cholesterol reduction on prostate weight and tumor progression**

Prostate weight was slightly, but not significantly, reduced in the ezetimibe group (0.39 g vs. 0.45 g; \( p = 0.275 \); Fig. 2a). However, as a continuous variable, higher serum cholesterol was significantly positively correlated with larger prostate size (\( p = 0.033 \); Fig. 2b).

In order to examine the effect of reducing serum cholesterol levels on prostate cancer progression, we classified prostate histology as normal, mPIN, invasive adenocarcinoma, or intracystic adenocarcinoma, according to the current guidelines [22]. By 4 months of age, all mice had developed both invasive and intracystic adenocarcinoma (Table 1), regardless of the dietary group. The rate of progression to invasive or intracystic adenocarcinoma did not vary significantly by the dietary group (Table 1).

**Effect of serum cholesterol on prostate tumor proliferation and apoptosis**

We used an automated digital pathology approach to quantify the rates of proliferation and apoptosis in tumor epithelium and tumor stroma separately, excluding the areas of normal prostate tissue, necrosis, and fluid-filled intracystic lesions (Supplementary Figures S3, S4, S5). We found that mice randomized to the ezetimibe diet had lower tumor epithelial proliferation than those randomized to HFHC at 4 months of age (Ki67 H score 19.6 vs. 25.4; \( p = 0.173 \); Fig. 3), although this association was not statistically significant. There was no difference in tumor epithelial apoptosis scores between the dietary groups (\( p = 0.528 \)). When serum cholesterol was examined as a continuous variable, there was a positive correlation between high serum cholesterol levels and increased tumor epithelial cell proliferation at 4 months (\( p = 0.069 \)), although this was not statistically significant, and a negative correlation between high serum cholesterol levels and tumor epithelial cell apoptosis (\( p = 0.004 \); Fig. 3). Restricting our analysis to the tumor stroma revealed that mice consuming ezetimibe diet had significantly reduced tumor stromal proliferation (\( p = 0.010 \)), although the rates of tumor stromal cell apoptosis did not differ between the dietary groups (\( p = 0.723 \); Supplementary Figure S6). However, serum cholesterol levels were significantly inversely correlated with tumor stromal cell apoptosis at 4 months (\( p = 0.048 \)), although the positive
Fig. 1 Caloric intake (a) and body weight (b) trajectories throughout the study duration in the PTEN-null transgenic mouse model of prostate cancer, median differences in serum cholesterol level between the dietary groups at 4 months of age (c), and correlation between body weight at 4 months of age and serum cholesterol levels (d).

Table 1 Effect of lowering serum cholesterol levels on prostate tumor progression in the PTEN-null transgenic mouse model

|                  | 2 months of age | 3 months of age | 4 months of age |
|------------------|-----------------|-----------------|-----------------|
|                  | Invasive adenocarcinoma, n (%) | Intracystic adenocarcinoma, n (%) | Invasive adenocarcinoma, n (%) | Intracystic adenocarcinoma, n (%) |
| HFHC             | 0 (0)           | 1 (14)          | 7 (78)          | 4 (44)          | 23 (100) | 23 (100) |
| Ezetimibe        | 0 (0)           | 0 (0)           | 8 (80)          | 3 (30)          | 25 (100) | 25 (100) |
The correlation between serum cholesterol levels and stromal proliferation was not significant ($p = 0.328$; Supplementary Figure S6). We investigated whether serum cholesterol levels modified tumor composition by quantifying the proportion of stromal tissue within the tumor, and found no significant differences between the dietary groups (data not shown).

**Effect of serum cholesterol levels on serum and prostate androgen concentrations**

Levels of serum and prostate androgens did not differ between the dietary groups at 4 months of age (data not shown). However, levels of prostate testosterone, DHT, DHEA, and androstenedione were positively correlated with serum cholesterol levels, although these associations were not significant (Table 2). Adjusting linear regression analyses for age at dietary randomization strengthened these associations, particularly for DHEA and androstenedione ($p = 0.043$ and $p = 0.031$, respectively). Serum testosterone levels were positively correlated with serum cholesterol levels at 4 months, and this association was strengthened after adjusting for age at dietary randomization ($p = 0.077$; Table 2), though it remained not significant.

**Discussion**

Obesity, a common disorder affecting approximately one third of US men [23], is associated with increased incidence of aggressive prostate cancer and elevated prostate cancer mortality [1]. While the association between obesity and prostate cancer is likely multifactorial, epidemiologic and preclinical evidence indicates a potential role for high cholesterol, an obesity-associated metabolic abnormality, in prostate cancer progression [24], though not all studies have found a link between cholesterol and prostate cancer [7]. Using an obese PTEN-null transgenic mouse model of prostate cancer, we show that lowering serum cholesterol levels reduced tumor proliferation, increased tumor apoptosis, lowered tumor androgen concentrations, and slowed prostate tumor growth. In contrast, we found that serum...
cholesterol reduction did not significantly affect the rate of adenocarcinoma development. Though our findings do not support a role for cholesterol lowering in slowing tumor development in the PTEN-null mouse model of prostate cancer, they do provide evidence for an effect of serum cholesterol on tumor androgen signaling and tumor growth. Future studies are needed to determine the potential role for cholesterol-lowering interventions in prostate cancer treatment.

The recognition of prostate cancer as an androgen-dependent disease [25] led to targeting the androgen signaling pathway as the mainstay of advanced prostate cancer treatment. While the disease is initially responsive to androgen-deprivation therapy, the majority of patients eventually go on to develop castration-resistant prostate cancer (CRPC), which is currently incurable. There is substantial evidence that achieving castrate levels of circulating androgens does not eliminate intraprostatic androgens, and that intratumoral de novo androgen synthesis from cholesterol may be an important source of these residual tumor androgens in castrate men [26, 27]. Indeed, statin use and lower cholesterol levels have been associated with lower levels of PSA [28, 29], whose gene is under the control of the androgen receptor, suggesting that cholesterol reduction may impact intraprostatic androgen signaling. Furthermore, some epidemiologic evidence supports a potential role for serum cholesterol level in response to androgen deprivation therapy. One study reported a shorter time to castrate-resistant prostate cancer development in men with elevated serum cholesterol levels at the time of androgen deprivation therapy, relative to those with normal cholesterol [30]. Another study demonstrated that statin use at initiation of androgen deprivation therapy delayed the progression to castrate-resistant prostate cancer [31]. In the present study, we demonstrate that reduction of serum cholesterol levels in a mouse model of prostate cancer decreased intratumoral androgen concentrations, adding support to epidemiologic and laboratory data that cholesterol-lowering strategies should potentially be explored alongside androgen-deprivation therapy in prostate cancer.

The PTEN-null mouse model mimics the clinical course of human prostate cancer, in addition to recapitulating histologic and molecular features of human disease [20]. PTEN loss is a genetic aberration frequently found in primary and metastatic human prostate cancer, and its loss is associated with poor prognosis [32]. Therefore, identifying factors that could improve outcomes in PTEN-null prostate cancer is of great importance. Though PTEN-null tumors in this mouse model regress following castration, they can also grow in the absence of androgen, enabling the study of both androgen-dependent and androgen-independent effects of serum cholesterol on prostate cancer development and growth [20]. Furthermore, one study found that PTEN deletion and subsequent activation of phosphoinositide-3-kinase (PI3K) signaling in prostate cancer cell lines caused accumulation of cholesterol from the surrounding environment that, in turn, increased the proliferative and invasive capacity of these cells [33]. As such, our findings combined with those from prior studies may support a role for cholesterol in PTEN-null prostate cancer, and suggest that human studies should examine the cholesterol-prostate cancer link within the context of PTEN-defined tumor subtypes.

This study should be considered in light of its limitations. Although statins are the most commonly prescribed cholesterol-lowering drugs in the clinic, they do not reduce serum cholesterol levels in mice [34]. As such, we achieved cholesterol reduction in our mouse model using the FDA-approved drug, ezetimibe, usually prescribed to human patients in conjunction with a statin or as a substitute in patients that cannot tolerate a statin. However, given the hepato-selectivity and low systemic bioavailability of statins, it may be that their effects on the prostate are predominantly mediated indirectly via reduction of systemic cholesterol levels [35]. Furthermore, the use of ezetimibe in

the present study enabled examination of the effect of cholesterol reduction on prostate cancer progression in the absence of changes to dietary composition and/or obesity status, both of which have been implicated in prostate cancer [1, 36]. Future studies should explore the effect of statin use and serum cholesterol reduction on intratumoral androgen signaling in humans. Finally, regarding our tumor growth measurements, we could not assess the contribution of fluid-filled intracystic lesions to tumor weight, and this may have biased our results. However, our finding that lowering serum cholesterol slowed tumor growth is also supported by our observation of decreased tumor cell proliferation and increased tumor cell apoptosis in mice with lower cholesterol levels, as determined by IHC assays. These limitations are balanced by an important strength of this study. Loss of the tumor suppressor, PTEN, is one of the most common genetic alterations in prostate cancer [20], making this a relevant mouse model with which to study this disease. In addition, the use of a transgenic mouse model enabled assessment of the effect of cholesterol reduction on prostate cancer progression within the native microenvironment, known to play a role in disease progression [37].

Cardiovascular disease and cancer are leading causes of mortality in Western society [38], and prostate cancer is the second most common cause of male cancer deaths in the US [39]. Therefore, understanding the role of hypercholesterolemia as a shared risk factor for these diseases has great public health importance. Furthermore, high cholesterol is a readily modifiable risk factor through the use of pharmaceutical agents and/or lifestyle modifications. Notably, we demonstrate that cholesterol reduction affects prostate cancer growth even within the context of diet-induced obesity, a known prostate cancer promoter. Together with epidemiologic evidence suggesting a potential role for hypercholesterolemia in promoting prostate cancer progression [8, 10], and for statins in preventing aggressive prostate cancer incidence and progression [13–15], these results support further studies exploring a role for cholesterol-lowering interventions in prostate cancer treatment.
