**ABSTRACT**

**Objective(s):** As not only few evidences but also contradictory results exist with regard to the effects of resistance training (RT) and resistance plus endurance training (ERT) on respiratory system, so the purpose of this research was therefore to study single and concurrent effects of endurance and resistance training on pulmonary function.

**Materials and Methods:** Thirty seven volunteer healthy inactive women were randomly divided into 4 groups: without training as control (C), Endurance Training (ET), RT, and ERT. A spirometry test was taken 24 hrs before and after the training course. The training period (8 weeks, 3 sessions/week) for ET was 20-26 min/session running with 60-80% maximum heart rate (HR max); for RT two circuits/session, 40-60s for each exercise with 60-80% one repetition maximum (1RM), and 1 and 3 minutes active rest between exercises and circuits respectively; and for ERT was in agreement with either ET or RT protocols, but the times of running and circuits were half of ET and RT.

**Results:** ANCOVA showed that ET and ERT increased significantly \( P<0.05 \) vital capacity (VC), forced vital capacity (FVC), and forced expiratory flows to 25%-75%; ET, RT and ERT increased significantly \( P<0.05 \) maximum voluntary ventilation (MVV); and only ET increased significantly \( P<0.05 \) peak expiratory flows (PEF); but ET, RT and ERT had no significant effect \( P>0.05 \) on forced expiratory volume in one second (FEV₁) and FEV₁/FVC ratio.

**Conclusion:** In conclusion, ET combined with RT (ERT) has greater effect on VC, FVC, FEF rating at 25%-75%, and also on PEF except MVV, rather than RT, and just ET has greater effect rather than ERT.

**Introduction**

Efficacy of respiratory and pulmonary functions has a direct relationship with general health (1). Furthermore, regular physical activity is of much importance for general health of people, especially young people (2, 3). Since cardiorespiratory endurance is a key component of physical fitness and physical activity can lead to physical fitness, so it can improve cardiorespiratory endurance (4). It is well-documented that the most effective factor in cardiorespiratory fitness is physical activity level (5-7). Exercise training improves endurance and strength of athletes’ respiratory muscles; it also causes resistance reduction in respiratory canals, and increases lung elasticity and alveolar expansion as studies have supported the expansion of pulmonary volumes and capacities (8). Accordingly, selection of appropriate type of exercise training may be an important factor in prevention or decrease of respiratory diseases and increase the efficacy of this system.
It has been proved that the inability to maintain ventilation with high levels is a factor for restricting maximal aerobic capacity in healthy people (9-11). Although some evidences have reported that the pulmonary system is un-affected by physical activity (12, 13), Crosbie, (2012) after a systematic review of randomized control trials (16 studies and 516 subjects met inclusion criteria), suggested that physical training increases aerobic capacity measured by $\text{VO}_{2\text{max}}$, and didn’t enhance pulmonary function in children with asthma (14); but it is mainly recommended in various researches that endurance training (ET) is appropriate for improvement of pulmonary function (15); and others found that body endurance is increased by respiratory trainings (16). On the other hand, the effects of RT on inspiratory and expiratory muscles has been investigated and it was concluded that they have positive impacts, both on healthy people and individuals with chronic obstructive pulmonary disease (15, 17, 18).

But recently parallel effects of ET and resistance training (RT) have been considered since the studies show further beneficial effects of strength training on improvement of ET function (19). There are some evidences related to RT (15) and parallel training effects on pulmonary function; these studies were done on patients with chronic obstructive pulmonary disease and showed a positive impact on pulmonary function indices (20, 21), but little study has been done on healthy individuals regarding the effect of inspiratory (IMT) (18, 22) and concurrent respiratory muscle training (CRMT) (17) [which are approximately equal to training regimens used in systemic exercise (22)] on pulmonary function and contradictory results have been reported different studies.

Besides, it is known that Iranian women have poor situations for active life style because of their religious beliefs. They might be at risk even if they are healthy. Considering the little evidence about the effect of RT and also endurance plus resistance training (ERT) (23) except healthy subjects specially healthy inactive women, as well as contradictory results of these reports, we aimed to investigate the parallel effects of ET and RT on pulmonary function of healthy inactive women. Therefore we selected four groups with three types of training and tried to keep the intensity and duration of these three types of training the same.

Materials and Methods

Subjects

The study was approved by the research ethics committee of the School of Medical Sciences of Islamic Azad University (Iran), and conducted in accordance with policy statement of the Declaration of Iranian Ministry of Health. Written informed consent was obtained from young inactive healthy women (20-35 years old) who registered in “Hirboud Sport Club” at recent summer (n = 85). All subjects were asked to complete a medical examination as well as a medical questionnaire to ensure that they were not taking any regular medications, and were free of cardiac, respiratory, allergic, eye and ear surgery, respiratory epidemic infections, uncontrolled blood pressure, thorax surgery history in three weeks before beginning trainings, history of pulmonary embolism, active hemoptysis, unstable angina, or myocardial infarction. Then, the acceptable volunteers (n = 36) were classified randomly into 4 groups as follows: a control group (n=9) without training (C), ET group (n=9), RT group (n=10), and ERT group (n=9).

Research design

Participants were taken to the practice hall two times before the beginning of training period. In the first session, their one repeat maximum (1RM) was determined for each of 8 exercises (bench press, curl up, arm extension, leg press, knee flexion, knee extension, plantar flexion, and sit up). In the second session, a spirometry test was performed on each participants (spirometer: Spiro lab, SN: A23-050-7460, Mir Co, Italia) for VC, FVC, FEV1, FEV1/FVC ratio, PEF, and MVV measurements. Also, $HR_{\text{max}}$ was calculated ($HR_{\text{max}} = 220 - \text{age}$) for each one and controlled with heartbeat determinant girdle (Phase, Germany) during training. The training sessions started 24 hrs after the spirometry test lasting for 8 weeks, that is three days a week (Saturday, Monday, and Wednesday).

Exercise training procedures

The subjects were instructed to follow a normal lifestyle, to maintain daily habits, and to avoid any regular medications. Each session contained 10 min-warm up and cool down. ET runs for 20 min/sessions with 60-65% $HR_{\text{max}}$ in the first 4 weeks and 26 min/session with 65-80% $HR_{\text{max}}$ in the second 4 weeks. RT training included two circuits/sessions, 60s (about 12 repeats) for each exercise with 60-65% 1RM, and 1 and 3 minutes specified to active rest between exercises and circuits respectively during the first 4 weeks; and four circuits/session, 40s (about 8 repeats) for each exercise with 65-80% IRM and same rest periods during the second 4 weeks. ERT exercises were in agreement with either ET or RT protocols, but the times of running and circuits was half of ET and RT, respectively (Table 1).

Statistics

We used ANCOVA to determine the effects of the mentioned three types of training at significance levels of $P=0.05$. Important ANCOVA assumptions, including linear relationship of dependent variable and covariate, normal distribution, and equality of error variances were examined by Pearson’s correlation test, one-sample
Kolmogorov-Smirnov test, and Levene test, respectively. In variables that assumptions of normal distribution and equality of error variances were not met, we first subtracted dependent variables (post-test) by covariates (pre-test) as new dependent variables. Thus the effects of covariates were removed; then we used Kruskal-Wallis test for k-independent samples, and Mann-Whitney test for paired comparisons as post-hoc test. Significance levels in these paired comparisons was $P=0.0083$ (Bonferroni adjustment for multiple comparisons).

Results

General data of subjects including age, and body mass index (BMI) are summarized in Table 2.

Assumptions of linear relationships and normal distribution were met in all variables; however, the one assuming equality of error variances was met only in VC (F = 1.98, $P=0.13$), FVC (F = 2.69, $P=0.061$), MVV (F = 0.69, $P=0.56$), and PEF (F = 1.49, $P=0.235$), but not in FEF 25%-75% (F = 5.93, $P=0.002$), FEV1 (F = 3.31, $P=0.031$), and FEV1/ FVC (F = 3.31, $P=0.031$).

In ANCOVA results, the adjusted mean of dependent variables (post-test in this study) are presented by omission of covariate (pre-test in this study) effects.

VC. The main effect of “Group” on VC was significant (F = 5.201, $P=0.005$). With respect to adjusted mean, ET and also ERT were significantly greater than RT and C. Other comparisons were not significant (Figure 1). It showed a 14.9%, 2.4%, 14.4%, and 3.4% elevation in ET, RT, ERT, and C, respectively. In other words, ET and ERT caused significant improvement in VC, but RT had no significant effect.

FVC. The main effect of “Group” on FVC was also significant (F = 9.235, $P=0.000$). ET was significantly greater than RT and C, and ERT was greater than C. Other comparisons were insignificant (Figure 2). It showed a 23.1%, 6.55%, 19.1%, and 3.2% increase in ET, RT, ERT, and C.

MVV. The main effect of “Group” on MVV was also significant (F = 4.966, $P=0.006$). ET was significantly greater than C, but other comparisons were not significant (Figure 4). It showed a 8.5%, 5.7%, 4.0%, and 2.04% elevation in ET, RT, ERT, and C, respectively. In other words, ET and ERT caused significant improvement in MVV, but RT had no significant effect.
Type of Training and Pulmonary Function

Iran J Basic Med Sci; Vol. 16, No. 4, Apr 2013

FEV1 and FEV1/FVC. Inter group differences for FEV1 and FEV1/FVC were not significant [(Chi-square = 7.55, P= 0.056) and (Chi-square = 2.327, P= 0.507), respectively] (Table 3). FEV1 showed a 10.7%, 10.4%, 5.6%, and 2.8% elevation in ET, RT, ERT and C respectively.

**Figure 2.** Between-group differences for Forced Vital Capacity (FVC). ET: endurance training. RT: resistance training. ERT: endurance plus resistance training. C: control without training. +: significantly greater than Resistance and Control group (p ≤ 0.05). *: significantly greater than Control group (p ≤ 0.05).

**Figure 3.** Between-group differences for Maximum Voluntary Ventilation (MVV). ET: endurance training. RT: resistance training. ERT: endurance plus resistance training. C: control without training. +: significantly greater than the other groups (p ≤ 0.05).

**Figure 4.** Between-group differences for Peak Expiratory Flows (PEF). ET: endurance training. RT: resistance training. ERT: endurance plus resistance training. C: control without training. *: significantly greater than Control group (p ≤ 0.05).

**Figure 5.** Between-group differences for Forced Expiratory Flows (FEF25%-75%). ET: endurance training. RT: resistance training. ERT: endurance plus resistance training. C: control without training. *: significantly greater than Control group (p ≤ 0.05).

FEV1 and FEV1/FVC. Inter group differences for FEV1 and FEV1/FVC were not significant [(Chi-square = 7.55, P= 0.056) and (Chi-square = 2.327, P= 0.507), respectively] (Table 3). FEV1 showed a 10.7%, 10.4%, 5.6%, and 2.8% elevation in ET, RT, ERT and C respectively; and, FEV1/FVC was increased for 1.45%, 0.8%, and 0.6%, in ET, RT, and ERT respectively and was decreased for 0.14% in C.
Discussion

In this study, the VC (equal to sum of expiratory reserve volume, inspiratory reserve volume, and flowing volume) in ET and ERT was significantly greater than that in RT and C, which was found after 8 weeks of training as compared to the baseline. On the other hand, the obtained results indicate that significant improvement in VC of ERT may be due to the effects of endurance training which are summed with the effects of resistance training. Also, the FVC, i.e. maximum amount of air exited from lung with a deep expiration after a deep inspiration, was significantly greater in ET than in RT and C, and was significantly greater in ERT than in C, which was found after 8 weeks of training as compared to the baseline. In other words, ET, and ERT caused significant improvement in FVC, but RT had no significant effect. As support of our results, researches have shown that active persons and athletes have a higher level of VC and FVC compared to healthy control group. Nourry et al. (2005) reported a significant increase in FVC of healthy prepubescent children after 8 weeks of high-intensity intermittent running training (26). Farid et al. (2005) found significant changes in FVC after eight weeks of aerobic exercise (asthmatic patients, 3 sessions/week, 20 min/session, 15 min warm up and tense exercise before main exercise/session) (27). Tartibian, Maleki, & Abbasi. (2010) found a significant increase in VC and FVC after wrestling training (12 weeks, 3 times/week, 90-120 min/day to 70-85% of HRmax in the first 6 weeks, and to 85-95% of HRmax in the second 6 weeks) (28). Enright and Unnithan. (2011) found an increase in VC after 8-week IMT program (80% of sustained maximum inspiratory effort, 3 times/week inconsecutively) (22). Shaw, and Brown. (2011), after 16 weeks aerobic (45 min, 60%HRmax), resistance (8 exercises, 60%RM, 3 sets, 15 repetitions) and concurrent training, found that both aerobic and concurrent training had an effect on improvement of some pulmonary functions, but concurrent training had the most effect on improvement of FVC, FEV1(1), PEF, and FEV25-75% (23) in sedentary male smokers.

In our study, the expansion of VC and FVC can be due to the high-rate ventilation during ET gravely requesting the respiratory muscles. However, VC is usually lower than VC (29). Therefore, the increase in FVC could result from an enhancement in contractility of expiratory muscle without real change in lung volume (30). But we observed a significant increase in VC.

Moreover, the MVV (total volume of air replaced with inspiration and expiration in maximum depth and speed) in ET, RT, and ERT was significantly greater than C after 8 weeks of training as compared to the baseline. In other words, ET, RT and ERT caused significant improvement in MVV. Farid et al (2005) reported that there was significant expansion in MVV (27). Tartibian et al (2010) also showed a significant increase in MVV (28). Galvan, & Catanoe. (2007) believe that MVV can indicate the function of only respiratory muscles and therefore, the values of MVV increase on account of improved strength of inspiratory muscles (31). But we know that MVV is maximum voluntary ventilation and not only inspiratory muscles but also expiratory muscles are involved in voluntary ventilation with strength; so depending on the force-generating capacity of inspiratory and expiratory muscles, strength of these muscles is improved during 8 weeks of ET, RT and ERT.

In addition, the PEF (maximum volume of air flow during a deep expiration maneuver) in ET, RT and ERT was significantly greater than that in C after 8 weeks of training as compared to the baseline. In other words, ET caused significant improvement in PEF as compared to other types of training. Nourry et al (2005) observed a significantly increased PEF after running training (26). Also, Farid et al (2005) found a significant expansion in PEF after eight weeks of aerobic exercise in asthmatic patients (27).

Furthermore, the FEF 25%-75% (volume of air flow exiting the lung during mid time of FVC) in ET, and ERT, toward RT was significantly greater than that in C after 8 weeks of training as compared to the baseline. In other words, ET and ERT caused significant improvement in FEF (25%-75%) as compared to RT. Farid et al (2005) and Tartibian et al (2010) both also found the significant increase in FEF (25-75%) after exercise training (27, 28).

Nevertheless, intergroup differences for FEV1 (volume in one second is volume of air that exits the lung in 1-s of a deep and potent expiration) and FEV1/FVC or the ratio of forced expiratory volume in 1-s to forced vital capacity (i.e. the percentage of FVC which exits the lung during first second of a deep expiration) were not significant after 8 weeks of training as compared to the baseline, especially to C; that is, each type of training could not significantly affect FEV1 and FEV1/FVC.

Grisbrook et al (2012), after a 12 - week goal directed interval and resistance training didn’t find any change in FEV1/FVC ratio of adults with burn (32). Cheng et al (2003) showed that active persons had a higher FEV1 than the others (24). Besides, Wright et al (2003) after a hypertrophic maximal strength training [12 weeks (2 weeks of muscle habituation training, 5 weeks of hypertrophic training 1, 5 weeks of hypotrophic training II with intensified eccentric work), initially twice, then 3 times a week, 60-120 min] in patients with chronic obstructive pulmonary disease (COPD) observed that FEV1 is elevated (5.3%) significantly compared to the baseline (15). Nourry et al (2005) and Tartibian, Maleki, & Abbasi. (2010) reported a significant increase in FEV1 6 days after training (26). Farid et al (2005) also found that there was a significant rise in FEV1, but FEV1/FVC showed no significant change (27).

Based on a literature, Nourry et al (2005) (26) interpreted that the improvement in expiratory flow parameters such as PEF, FEF (25%-75%), FEV1, and FEV1/FVC could be il-
increase in VC, FVC, MVV, and FEF (25%-75%) as did ET. Also, serum cortisol has also been reported to have a connection to bronchodilatation and increasing airflow (39, 40). Cortisol (41) also seems to be feasible. A decreased lung and thorax elasticity (8, 28). On the other hand, hormones and strengthened respiratory muscles as well as lung and thorax elasticity (8, 28). On the other hand, hormonal effects, compromised roles of adrenaline (39, 40) and cortisol (41) also seem to be feasible. A decreased lung retractability and induced vasodilatation of pulmonary vessels are reported to be due to an increased activation of adrenaline system during exercise training in which vasodilatation of pulmonary vessels cause a decreased airway resistance and an enhanced FEV1 and FVC through increasing airflow (39, 40). Serum cortisol has also been reported to have a connection to bronchodilatation and lung surfactant generation (41).

Conclusion

This study showed that a period of ERT caused a clear increase in VC, FVC, MVV, and FEV1 (25%-75%) as did ET. Also, PEF is elevated only due to ET; and RT improved only MVV as did ET and ERT in healthy young inactive women. FEV1 and FEV1/FVC were not affected significantly by any types of training. Results of our study may suggest that the type of training is related to the improvement of pulmonary function; however ET, RT and ERT have no difference in influence on VC, MVV, FEF 25%-75%, PEF, FEV1 and FEV1/FVC, but because ET caused an increase in VC, FVC, MVV, FEF 25%-75% and PEF, and RT added to ET (ERT) caused an increase in VC, FVC, MVV, FEV1 25%-75%, we can conclude that ET has probably higher effects on some pulmonary function of healthy young inactive women as compared to not only RT but also to ERT.

Acknowledgment

We wish to thank Dr Fatemeh Salami and Dr Parvaneh Nazar Ali, for their kind help and sincere advice. We also thank all volunteers and the manager of "Hirboud Sport Club" for their participation in this study.
