ABSTRACT

We present Chandra and XMM-Newton X-ray observations that monitor the neutron star cooling of the quasi-persistent neutron star X-ray transients KS 1731–260 and MXB 1659–29 for approximately 4 years after these sources returned to quiescence from prolonged outbursts. In both sources the outbursts were long enough to significantly heat the neutron star crust out of thermal equilibrium with the core. We analyse the X-ray spectra by fitting absorbed neutron star atmosphere models to the observations. The results of our analysis strengthen the preliminary findings of Wijnands et al. that in both sources the neutron star crust cools down very rapidly suggesting it has a high heat conductivity and that the neutron star core requires enhanced core cooling processes. Importantly, we now detect the flattening of the cooling in both sources as the crust returns to thermal equilibrium with the core. We measure the thermal equilibrium flux and temperature in both sources by fitting a curve that decays exponentially to a constant level. The cooling curves cannot be fit with just a simple exponential decay without the constant offset. We find the constant bolometric flux and effective temperature components to be \(9.2\pm0.9\) \(\times\) \(10^{-14}\) ergs cm\(^{-2}\) s\(^{-1}\) and 70.0 \(\pm\) 1.6 eV in KS 1731–260 and \((1.7\pm0.3)\times10^{-14}\) ergs cm\(^{-2}\) s\(^{-1}\) and 51.6 \(\pm\) 1.4 eV in MXB 1659–29. We note that these values are dependent on the assumed distance to the sources and the column density which was tied between the observations due to the low number of photons in the latter observations. However, importantly, the shape of the cooling curves is independent of the distance assumed. In addition, we find that the crust of KS 1731–260 cools faster than that of MXB 1659–29 by a factor of \(\sim2\), likely due to different crustal properties. This is the first time that the cooling of a neutron star crust into thermal equilibrium with the core has been observed in such detail.

Key words: accretion, accretion discs — X-rays: binaries — stars: neutron — X-rays: individual (KS 1731–260), X-rays: individual (MXB 1659–29)

1 INTRODUCTION

Low-mass X-ray binaries consist of either a neutron star or a black hole that accretes matter from a low-mass companion star, where mass transfer occurs because the donor star overflows its Roche-lobe. The soft X-ray transients form a sub-group of low-mass X-ray binaries. The vast majority of their time is spent in a quiescent state where little accretion occurs, resulting in X-ray luminosities < \(10^{34}\) ergs s\(^{-1}\). However, during outbursts (which usually last weeks to months) the mass-accretion rate rises significantly, with a corresponding large increase in brightness - the typical outburst luminosity is in the range \(10^{36} – 10^{39}\) erg s\(^{-1}\) (for reviews of neutron star and black hole transients see, e.g., Campana et al. 1998, Remillard & McClintock 2006).

The quiescent X-ray spectra of neutron-star X-ray transients can generally be characterised by two components - a soft, thermal component that dominates below a few keV, and a hard power-law tail that dominates above a few keV. The power-law component is not always present.
and its origin is poorly understood, though in some systems it completely dominates (e.g. EXO 1745–248 in the globular cluster Terzan 5. Wijnands et al. 2005a). Several emission mechanisms have been proposed to explain the quiescent X-ray emission, for example, residual accretion onto the neutron star magnetosphere or pulsar shock emission (e.g. Campana et al. 1998a; Menou et al. 1998; Campana & Stella 2001; Menou & McClintock 2001). However, the mechanism most often used to explain the thermal X-ray emission is that in which the emission is due to the cooling of a hot neutron star which has been heated during outburst (van Paradijs et al. 1997; Brown et al. 1998). In the Brown, Bildsten & Rutledge (1998) model, the neutron star core is heated by nuclear reactions occurring deep in the crust due to accretion during outburst, and this heat is released as thermal emission during quiescence. Thus, the temperature of the neutron star core and surface in quiescence is then set by the time-averaged mass accretion rate and the neutron star properties. Therefore, if the time-averaged accretion rate can be estimated, studying quiescent neutron star systems can give important information about the physical processes at work in the very high densities present in neutron star cores.

Some X-ray transients (the quasi-persistent transients) spend an unusually long time in outburst, with outbursts lasting years to decades rather than the more common weeks to months. For the neutron-star quasi-persistent transients, during outbursts, the crust of the neutron star is heated to a point beyond thermal equilibrium with the stellar interior. Once accretion falls to quiescent levels, the crust cools thermally, emitting X-rays, until it reaches equilibrium again with the core (e.g., Rutledge et al. 2002a). Crust cooling curves allow us to probe the properties of neutron stars, such as, the kind of core cooling processes at work (which depends on the equation of state of ultra dense matter) and the heat conductivity of the crust (which likely depends on the properties of the iron lattice of the crust, such as its purity). While it is expected that the crust can cool significantly between outbursts, the neutron star core should only cool significantly on much longer timescales. X-ray observations of the two quasi-persistent neutron star X-ray transients KS 1731−260 (Wijnands et al. 2001a; Wijnands 2002; Wijnands et al. 2002a; Rutledge et al. 2002a; Wijnands et al. 2005; Rutledge et al. 2002a) and MXB 1659−29 (Wijnands et al. 2003a; Wijnands 2004; Wijnands et al. 2004) have tracked the initial cooling of these neutron stars once they went into a quiescent state. In this paper, we present additional Chandra and XMM-Newton observations that further track the cooling of these two neutron stars as they return to thermal equilibrium with the core.

1.1 KS 1731−260

KS 1731−260 was first detected in outburst in August 1989 by the Mir-Kvant instrument and further analysis revealed that the source was also found to be active in October 1988 (Sunyaev et al. 1988; Sunyaev et al. 1990a). As no previous telescopes had detected this source, it was classified as a soft X-ray transient and the detection of type I X-ray bursts identified the compact object as a neutron star. Since then, until early 2001, the source remained bright and was observed by many X-ray telescopes including the ART-P and SIGMA telescopes aboard GRANAT, Ginga, ROSAT, RXTE, ASCA, and BeppoSAX (Sunyaev 1990b, 1990a; Barret et al. 1992; Yamauchi & Koyama 1990; Barret et al. 1998; Smith et al. 1997; Wijnands & van der Klis 1997; Muno et al. 2000; Narita et al. 2001; Kunikers et al. 2002). In early 2001, KS 1731−260 was undetected by monitoring observations by the All-Sky Monitor (ASM) on-board the Rossi X-ray Timing Explorer (RXTE) as can be seen by the ASM lightcurve of this source in Fig. 1 (top). Further pointed RXTE observations with the Proportional Counter Array (PCA) and the bulge scan observations of the Galactic centre region did not detect the source, with the first non-detection by the PCA observations on 2001 February 7 (Wijnands et al. 2001a). Using archival RXTE/PCA data, we find that the final detection of the source with RXTE was on 2001 January 21, thus it was still in outburst and actively accreting on this date. We extracted the RXTE X-ray spectrum of the source on that day and find that a 2-10 keV unabsorbed flux of $\sim 2.3 \times 10^{-10}$ erg cm$^{-2}$ s$^{-1}$ which corresponds to a luminosity of $\sim 1 \times 10^{36}$ erg s$^{-1}$ for a distance of 7 kpc (we assume a distance to KS 1731−260 of 7 kpc throughout the paper, Muno et al. 2000). Thus, KS 1731−260 went into a quiescent state sometime after 2001 January 21 and it was actively accreting for around 12.5 years. This last detection in outburst gives a much better constraint than had previously been found for when this source turned off. Unfortunately, there are no other known outbursts of this source, thus we are unable to tell whether this is a typical outburst for this source, or whether previous outbursts have been significantly longer or shorter.

Within two months of KS 1731−260 going into a quiescent phase there was a 20 ks Chandra Advanced CCD Imaging Spectrometer (using ACIS-S mode) observation of this source on 2001 March 27 (Wijnands et al. 2001a). These authors detected the source at an unabsorbed flux of $\sim 2 \times 10^{-13}$ ergs cm$^{-2}$ s$^{-1}$ (0.5-10 keV), which corresponds to a 0.5-10 keV luminosity of $\sim 1 \times 10^{33}$ ergs s$^{-1}$, a factor...
of $10^4$ lower than at the last RXTE/PCA detection. Observations by BeppoSAX confirmed the low flux of the source (Burderi et al. 2002) reported by Wijnands et al. (2001a), Wijnands et al. (2001b) note that this luminosity is much lower than expected if this is due to the cooling of the neutron star unless the source spends an unusually long amount of time in a quiescent state (at least several hundred years) and even longer if the crust is dominating emission from the neutron star, or that alternatively, enhanced cooling of the core occurs due to higher levels of neutrino emission. Rutledge et al. (2002a) note that given the long outburst, the crust would be dominating the thermal emission from the neutron star as it would have been heated significantly out of equilibrium with the core. Given the accretion history of this source (Rutledge et al. 2002a) simulate the quiescent lightcurve for the source, finding that depending on the crust and core microphysics, the cooling timescale for the crust to return to equilibrium with the core ranges from 1 to 30 years.

Additional X-ray observations of this source in quiescence with XMM-Newton in 2001 September 13-14 revealed that the source had dimmed further to a 0.5-10 keV luminosity of approximately $2 - 5 \times 10^{32}$ ergs s$^{-1}$ (Wijnands et al. 2002c). Under the neutron star cooling model, this decrease in luminosity is interpreted as rapid cooling of the the neutron star crust (a factor a $\sim 2-3$ in just half a year) suggesting that the crust has a high thermal conductivity and that enhanced core cooling processes are required for the core to be so cool. Preliminary analysis of two extra Chandra observations of this source on 2003 February 11 and 2003 August 8 yet again showed a further decrease in the luminosity of the source with a possible flattening of the luminosity cooling curve suggesting that the crust may have returned to equilibrium with the core (Wijnands 2003). In this paper we present the final analysis of these Chandra data, re-analyse all the previous Chandra and XMM-Newton observations of this source in quiescence and also present 2 additional Chandra observations and 1 additional XMM-Newton observation of this source.

1.2 MXB 1659–29

MXB 1659–29 is an X-ray transient discovered by Lewin et al. (1974) with SAS-3 in 1976 October. Type-I X-ray bursts detected by these initial observations established that the compact object was a neutron star. Between 1976 October and 1978 September, this source was detected several times by both SAS-3 and HEAO 1 (Lewin et al. 1978, Share et al. 1978, Griffiths et al. 1978, Dossey et al. 1978, Cominsky et al. 1983, Cominsky & Wood 1984, 1985). The source exhibits X-ray eclipses and dips with a period of $\sim 7.1$ hr, due to the orbital period (Cominsky & Wood 1984, 1985). In 1979 July, the Hokusai satellite failed to detect the source (Cominsky et al. 1983), and later observations by EXOSAT and ROSAT (Oosterbroek et al. 2001) failed to detect the source also. The 0.5-10 keV upper limit on the unabsorbed flux from the ROSAT observations in 1991 and 1992 is $(1 - 2) \times 10^{-14}$ ergs cm$^{-2}$ s$^{-1}$ (Verbunt 2001, Wijnands et al. 2002, Oosterbroek et al. 2001).

The source remained in a quiescent state for a period of 21 years, until on 1999 April 2 BeppoSAX detected the source in outburst again (van der Zande et al. 1999). This outburst was also detected by the RXTE ASM (see the ASM lightcurve in Fig. 1 and studied in detail by pointed observations with the RXTE/PCA, BeppoSAX and XMM-Newton (Wachter et al. 2000, Oosterbroek et al. 2001, Sidoli et al. 2001, Wijnands et al. 2001b, 2002a).

After an outburst of approximately 2.5 years in length, MXB 1659–29 went back into a quiescent state in 2001 September. The last detection of the source was on 2001 September 7 with the RXTE PCA, and the source was not detected on 2001 September 14, 24, 30 (Wijnands et al. 2002c). Just over a month after the source returned to a quiescent state, Chandra observations, on 2001 October 15, detected it with an unabsorbed 0.5-10 keV flux of $(2.7 - 3.6) \times 10^{-13}$ ergs cm$^{-2}$ s$^{-1}$ which corresponds to a 0.5-10 keV luminosity of $(3.2 - 4.3) \times 10^{32}$ ergs s$^{-1}$ for a distance of 10 kpc (Wijnands et al. 2002a). This flux is a factor greater than 10 higher than the ROSAT non-detection upper limit during quiescence in the early 1990s, suggesting that the emission is dominated by thermal emission from the neutron star crust that has been heated significantly out of thermal equilibrium with the core. However, as in the case of KS 1731–260, the flux was lower than expected given the accretion history, suggesting that enhanced cooling processes are occurring in the core. Further Chandra observations of MXB 1659–29 in quiescence on 2002 October 15 and 2003 May 9 showed that the flux was decaying exponentially, with the source flux decreasing by a factor of 7-9 over the 1.5 years between the 2001 and 2003 Chandra observations (Wijnands et al. 2004, Wijnands 2004, 2005). This is consistent with the accretion-heated crust cooling down in quiescence. The rapid timescale of the cooling implies that the crust may have a large thermal conductivity (Wijnands et al. 2004, Wijnands 2004, 2005). In this paper we re-analyse all the previous observations of this source in quiescence with Chandra and also present 2 additional Chandra observations and 1 additional XMM-Newton observation of this source.

2 OBSERVATIONS AND ANALYSIS

2.1 KS 1731–260

Here we analyse 5 Chandra and 3 XMM-Newton observations of KS 1731–260 in a quiescent state spread over ~4 years since the end of the outburst in 2001 February. Details of all the observations are given in Table I. We will first describe the analysis of the Chandra and then the XMM-Newton data.

2.1.1 Chandra analysis

All the Chandra observations were taken in ACIS-S configuration. The Chandra data were reprocessed and analysed using CIAO (v3.3) and CALDB (v3.2.1) following the standard analysis threads. For all of the Chandra observations, the source lightcurve and spectrum was extracted from a circle of radius 3″ around the source position, and the background lightcurve and spectrum was extracted from a source-free annulus with inner radius 7″ and outer radius 25″. We checked the background lightcurve for significant background flares, and none were found. The background-
Table 1. Details of the Chandra (CXO) and XMM-Newton (XMM) observations of KS 1731—260. The XMM-Newton observations 0137950201 and 0137950301 were so close in time that they were merged together. Here we give the details for the merged data. The background-subtracted net count rate is for the 0.5-10 keV band.

| ObsID (Telescope) | Date            | Good Time (ks) | Net Count Rate (counts s⁻¹) |
|-------------------|-----------------|----------------|----------------------------|
| 2428 (CXO)        | 2001 March 27   | 19.4           | (9.0 ± 0.7) × 10⁻³         |
| 0137950201/301 (XMM) | 2001 September 13/14 | 46.0 (MOS1) (1.7 ± 0.2) × 10⁻³ (MOS1) |
|                   |                 | 46.1 (MOS2) (2.0 ± 0.2) × 10⁻³ (MOS2) |
|                   |                 | 33.8 (pn) (3.7 ± 0.4) × 10⁻³ (pn)    |
| 3796 (CXO)        | 2003 February 11| 29.7           | (1.4 ± 0.2) × 10⁻³         |
| 3797 (CXO)        | 2003 August 8   | 29.7           | (1.1 ± 0.2) × 10⁻³         |
| 0202680101 (XMM)  | 2005 February 28/March 1 | 70.0 (MOS1) (2.4 ± 1.6) × 10⁻⁴ (MOS1) |
|                   |                 | 70.0 (MOS2) (6.4 ± 1.7) × 10⁻⁴ (MOS2) |
|                   |                 | 46.0 (pn) (1.1 ± 0.4) × 10⁻³ (pn)    |
| 6279 (CXO)        | 2005 May 10     | 10.4           | (0.5 ± 0.3) × 10⁻³         |
| 5468 (CXO)        | 2005 June 4     | 38.5           | (0.8 ± 0.2) × 10⁻³         |

Subtracted net count rates in the 0.5-10 keV band are given in Table 1.

2.1.2 XMM-Newton analysis

The first two XMM-Newton observations were separated by only a matter of hours, therefore we combine both of these together to increase sensitivity (as did Wijnands et al. 2002a). Here we analyse data from the three EPIC instruments on-board XMM-Newton - the two metal oxide semiconductor (MOS) cameras and the pn camera which were operated in full-frame mode with the thin filter in all the observations. To analyse the XMM-Newton data we use the Science Analysis Software (sas, version 6.5.0). We extract source lightcurves and spectra from a circle of radius 10″. The background extraction region was chosen to be a source-free circle of radius 1″ close to the source position. An annulus was not used because of the location of a nearby source, 2MASS J173412.7-260548, approximately 30″ away. Although this source is also present in the Chandra data the significantly better angular resolution of Chandra allows the use of an annulus for background extraction.

In the merged observations (ObsID 0137950201/301) background flares were present. We kept all data where the count rate for PI > 10 keV was less than 10 counts s⁻¹ for both the MOS and pn. In the last XMM-Newton observation (ObsID 0202680101) background flares were also present. In this case we kept all data where the count rate for PI > 10 keV was less than 10 counts s⁻¹ for the MOS and less than 15 counts s⁻¹ for the pn. We note that in this last observation the source is not obviously present when viewing an image in the full energy range. It only becomes apparent when restricting the energy range to between 1 and 2 keV where the vast majority of the photons from the source are emitted during this observation. The net count rates for these observations are given in Table 1.

2.1.3 Spectral analysis

For spectral analysis of the data we use xspec (Arnaud 1996). The data was fit with an absorbed neutron star hydrogen atmosphere model (nonmagnetic case, Zavlin, Pavlov & Shibanov 1995; Pavlov, Shibanov & Zavlin 1991) with the mass and radius fixed at the canonical values (1.4 M⊙ and 10 km respectively). Both the Chandra and XMM-Newton data were fit simultaneously with the column density tied between the observations and the temperature left as a free parameter. The column density was tied between the observations as there were too few counts in the last observations to constrain this parameter. The parameters for the EPIC MOS1, MOS2 and pn spectra for each XMM-Newton observation were all tied. The normalisation of the neutron star atmosphere model was fixed for a distance of 7 kpc (distance determined by Muno et al. 2003). Although this distance is uncertain, if this parameter is left free it goes to an unrealistic value that would put the distance to the source at ∼ 20 kpc (although the error on the distance is very large and includes the assumed 7 kpc distance). Hence, we chose to fix the distance at 7 kpc.

The data were unbinned, due to the low number of counts in the last few observations, and the W statistic (Wachter et al. 1979) was used in the spectral fitting process with background subtraction. The W statistic is adapted from the Cash statistic (Cash 1979), but allows background subtraction. We note that spectral fitting to the first Chandra observation using both χ² and W-statistics resulted in the same parameters to within the errors. To determine the bolometric flux we extrapolated the model to the energy range 0.01 - 100 keV, which gives approximate bolometric fluxes. The results of the spectral fits are detailed in Table 2. The spectral parameters for the first Chandra and XMM-Newton observations are consistent with those determined by Wijnands et al. (2002a). We also note that we get results consistent with the previously published data for KS 1731—260 (Wijnands et al. 2002a) when using alternative models to the NSA model (i.e., a blackbody model).

2.1.4 Cooling curves

It is clear from Table 2 that both the effective temperature for an observer at infinity (T_eff) and the bolometric flux F_{bol} decrease significantly with time. This cooling cannot be fit by a simple exponential decay, giving reduced χ² values of

© 0000 RAS, MNRAS 000, 000–000
4.3 and 4.8 for fits to the temperature and flux curves (see the dotted curves in Fig. 2). However, it is fit well by an exponential decay that levels off to a constant offset of the form \( y(t) = a \exp\left[-\left(t - t_0\right)/b\right] + c \), with \( a \) a normalisation constant, \( b \) the e-folding time, \( c \) a constant offset, and \( t_0 \) the start time. When fitting to the data, \( t_0 \) was fixed to midday on the last day that the source was observed to be active, MJD 51930.5, though we find that the other parameters are not very sensitive to the exact value of \( t_0 \). The best-fitting cooling curves are shown in Fig. 2. For the \( T_{\text{eff}}^{\infty} \) curve \( a = 39.5 \pm 3.6 \) eV, \( b = 325 \pm 101 \) days, and \( c = 70.0 \pm 1.6 \) eV, with \( \chi^2 = 0.2 \). For the \( L_{\text{bol}} \) curve \( a = (4.3 \pm 0.5) \times 10^{-13} \) ergs cm\(^{-2}\) s\(^{-1}\), \( b = 212 \pm 60 \) days, and \( c = (9.2 \pm 0.9) \times 10^{-14} \) ergs cm\(^{-2}\) s\(^{-1}\), with \( \chi^2 = 0.4 \). The reason for the difference between the e-folding times of the flux and effective temperature curves is explained in Appendix A.

### 2.2 MXB 1659–29

We analyse 5 Chandra observations and 1 XMM-Newton observation of MXB 1659–29 whilst the source was in a quiescent state spanning a period of \( \sim 4 \) years after the end of the outburst in September 2001. Details of the observations are given in Table 2. We will first describe the Chandra and then the XMM-Newton data reduction and analysis.

#### 2.2.1 Chandra analysis

All the Chandra observations of this source were taken in the ACIS-S configuration. As in the analysis of the Chandra data for KS 1731–260, we reprocess and analyse the data using CIAO (v3.3), CALDB (v3.2.1) and the standard analysis threads. For all of the Chandra observations, the source lightcurve and spectrum was extracted from a circle of radius 3″ around the source position, and the background lightcurve and spectrum was extracted from a source-free annulus with inner radius 7″ and outer radius 22″. We checked the background lightcurve for significant background flares, and none were found.

The analysis of the data for MXB 1659–29 is complicated by the fact that this source is eclipsing with an eclipse duration of \( \sim 900 \) s and period of 7.1 hr (Cominsky & Wood 1984, 1984; Wachter et al. 2000; Oosterbroek et al. 2001), and so we receive no (or minimal at most) counts from the source during the eclipse in quiescence (Wijnands et al. 2003). While there are enough counts in the first Chandra observation to detect the eclipse in the lightcurve (Wijnands et al. 2003), this is impossible with later observations and so we manually reduce the exposure time by 900 s to compensate for the source being in eclipse, having checked that only one eclipse occurs during each observation using the ephemeris of Oosterbroek et al. (2001). The

### Table 2. Neutron star atmosphere model fits to the X-ray spectrum of KS 1731–260 for 5 Chandra (CXO) and 3 XMM-Newton (XMM) observations. Luminosity is calculated assuming a distance to the source of 7 kpc. 1-σ errors on the parameters are given. The Modified Julian Date (MJD) given correspond to the mid-point of the observation. Note the column density parameter is tied between the observations when simultaneously fitting the data, and we determine \( N_H = (1.3 \pm 0.1) \times 10^{22} \) cm\(^{-2}\).

background-subtracted net count rates in the 0.5-10 keV band are given in Table 3.

### 2.2.2 XMM-Newton analysis

To analyse the XMM-Newton observation of MXB 1659–29 we use SAS (version 6.5.0). We analyse data from the EPIC MOS1, MOS2 and pn cameras which were operated in full-frame mode with the medium filter (the source is too faint to be detected on the RGS). The source lightcurve and spectrum was extracted from a circle with a 15′′ radius. The source lightcurve and spectrum was extracted from a circle with a 15′′ radius. The background lightcurve and spectrum was extracted from a source-free annulus with inner radius of 40′′ and outer radius of 100′′. Several background flares were present during the observation. We chose to keep all data where the count rate for PI > 10 keV was less than 7 counts s$^{-1}$ for the MOS and less than 10 counts s$^{-1}$ for the pn detector. Using the ephemeris of Oosterbroek et al. (2001) we determined that 3 eclipses occurred during the good time of the MOS observations, and so we manually reduce the exposure times for the MOS observations by 2.7 ks. In the pn observations several flaring events occurred during the eclipse times. We determine the total amount of good time for the pn during the eclipses to be 1.675 ks, and thus we reduce the exposure time by this amount. The net count rates for this XMM-Newton observation are given in Table 3.

### 2.2.3 Spectral analysis

We perform a similar spectral analysis for the MXB 1659–29 data as for the KS 1731–260. The Chandra and XMM-Newton spectra are left unbinned and fit simultaneously with an absorbed non-magnetic neutron star hydrogen atmosphere model using the W statistic with background subtraction. The column density is tied between the separate observations, the mass and radius fixed at their canonical values, and the temperature was the only parameter left free between the observations. The parameters are tied between the MOS1, MOS2 and pn spectra of the XMM-Newton observation. The distance to this source is in the range 10-13 kpc [Muno et al. 2001; Oosterbroek et al. 2001]. When leaving the normalisation as a free parameter in the Chandra fits this leads to a distance to the source of 7.8 kpc with no constraint on the upper limit of the distance and a lower limit of 6.2 kpc. So that the uncertainty in the distance does not dominate the uncertainties in the other parameters, we fix the normalisation of the neutron star atmosphere for a distance of 10 kpc. Spectral parameters determined by these fits are detailed in Table 4. The parameters we find for the first three Chandra observations which were previously analysed by Wijnands et al. (2001) are consistent with the values these authors determined when assuming the same distance.

### 2.2.4 Cooling curves

From the spectral fitting we find that both $T_{bol}^{29}$ and $F_{bol}$ decrease significantly with time after the end of the outburst. We measure an unabsorbed 0.5 - 10 keV flux of $6.3_{-2}^{+2} \times 10^{-15}$ ergs cm$^{-2}$ s$^{-1}$ during the last Chandra observation which is now lower than the upper limit from the previous non-detection with ROSAT in the early 1990s when the source had been in quiescence for over 10 years. As with KS 1731–260 this cooling cannot be fit by a simple exponential decay curve, giving reduced $\chi^2$ values of 17.5 and 13.6 for fits to the temperature and flux curves (see dotted line in Fig. 4). The cooling curves require an exponential decay which levels off to a constant of the form $y(t) = a \exp\left[-(t-t_0)/b\right] + c$. When fitting to the data, $t_0$ was fixed to midday on the last day that the source was observed to be active, MJD 52159.5. The best-fitting cooling curves are shown in Fig. 3. For the $T_{bol}$ curve $a = 75.0 \pm 2.8$ eV, $b = 505 \pm 59$ days, and $c = 51.6 \pm 1.4$ eV, with $\chi^2_p = 0.5$. For the $F_{bol}$ curve $a = (4.5 \pm 0.2) \times 10^{-13}$ ergs cm$^{-2}$ s$^{-1}$, $b = 242 \pm 13$ days, and $c = (1.7 \pm 0.3) \times 10^{-14}$ ergs cm$^{-2}$ s$^{-1}$, with $\chi^2_p = 0.5$.

### 3 DISCUSSION

We have presented Chandra and XMM-Newton observations monitoring two quasi-persistent neutron star X-ray transients (KS 1731–260 and MXB 1659–29) in a quiescent state. The long accretion episodes onto both of these neutron stars before they went into quiescence significantly heated the neutron star crust out of equilibrium with the core. The monitoring observations cover a period of ~4 years since the sources returned to quiescence. Spectral fitting with an absorbed neutron star hydrogen atmosphere model to the data has clearly shown both of them cooling exponentially over time. From the initial results of this monitoring Wijnands et al. (2002a, 2004) and the preliminary results of Wijnands (2003) it was not clear whether either of the neutron star crusts had reached thermal equilibrium with the

KS 1731–260 initially decreased by a factor of 2 in bolometric flux over the first half a year. Over the ~4 years since the source went into quiescence it has decreased in flux by a factor of ~5. It reached this level ~2.5 years after the end of the outburst and has remained at it since then, indicating that the crust returned to equilibrium with the core in this amount of time. This base level is set by the temperature of the core, which depends on the time-averaged mass accretion rate onto the source over thousands of years. Fitting an exponential decay with a constant offset to the data we get the equilibrium temperature to be 70.0 ± 1.6 eV, and the base bolometric flux level due to thermal emission from the core as $(9.2 \pm 0.9) \times 10^{-14}$ ergs cm$^{-2}$ s$^{-1}$, which corresponds to a luminosity of $(5.4 \pm 0.5) \times 10^{32}$ ergs s$^{-1}$. The $e$-folding times of the exponential decay were determined to be 325 ± 101 days for the temperature cooling curve and 212 ± 60 days for the flux cooling curve.

MXB 1659–29 decreased by a factor of 4 in bolometric flux over the first year after going into quiescence, and by a factor of 24 over the ~4 years of monitoring. Rutledge et al. (2004) found no evidence after the first 3 Chandra observations of this source that the temperature or flux was reaching a level set by the temperature of the core. The additional last 2 Chandra observations presented here indicate that the rate of cooling has decreased. Fitting an exponential decay with a constant offset to the data reveals that it has reached the base level which we determine to be 51.6 ± 1.4 eV for the temperature and $(1.7 \pm 0.3) \times 10^{-14}$ ergs cm$^{-2}$ s$^{-1}$ for the bolometric flux, which corresponds to a luminosity of $(2.0 \pm 0.4) \times 10^{32}$ ergs s$^{-1}$ (assuming d=10 kpc). The $e$-folding times of the exponential decay were determined to be 505 ± 59 days for the temperature cooling curve and 242 ± 13 days for the flux cooling curve.

Rutledge et al. (2002b) calculated detailed cooling curves for KS 1731–260 predicting the behaviour of the quiescent thermal emission from the neutron star given the source’s accretion history (see their fig. 3). Their models compare how the emission could evolve for standard versus enhanced core cooling and low versus high crust thermal conductivity. These authors find that regardless of the core cooling, if the crust has a low thermal conductivity, then the crust should dominate emission over the core for ~30 years, after which time there is a large drop in the source luminosity. For high-conductivity crusts the timescale for this transition is much shorter, ~1 year. Comparing these timescales to the observed cooling of KS 1731–260, then, in the con-
text of these models, the crust in this source must have a high thermal conductivity \cite{Wijnands2002a,Wijnands2003}, suggesting that it may be made of a pure iron lattice as increasing levels of impurity lower the conductivity. Unfortunately no detailed cooling curves have been calculated for MXB 1659–29. As the cooling is dependent on the accretion history of the source, we cannot directly compare the cooling of MXB 1659–29 with the model curves calculated for KS1731–260 by \cite{Rutledge2002}. However, in these models to see a rapid drop in flux within a few years of the source going into quiescence the crust must have a high conductivity, though there may be other physical processes in the crust that allow it to cool rapidly. In particular, we note that the \cite{Rutledge2002} models do not include Cooper-pair neutrino emission in the crust which will change the behaviour significantly \cite[e.g.,][]{Yakovlev1999}. See the discussion in \cite{Jonker2004} for further comment on this difference.

Once the crust has cooled, the quiescent luminosity is set by the emission from the hot core \cite{Rutledge2002}. In the standard core cooling mechanisms the heat lost by neutrino emission is negligible and thus the heat deposited in the star is radiated as thermal emission. In the case where enhanced core cooling is allowed, the enhanced level of neutrino emission, via the direct Urca process or Cooper-pairing, means that the vast majority of heat deposited escapes as neutrinos \cite{Colpi2001,Ushomirsky2001,Rutledge2002,Gusakov2004}. If enhanced core cooling occurs, then the quiescent luminosity set by the core temperature is significantly lower than if only standard core cooling occurs. We note that continued cooling is predicted in the \cite{Rutledge2002} models after the crust and core are in equilibrium. However, this cooling is at a significantly slower rate.

Importantly, in both sources we have now measured the thermal equilibrium temperature, which is set by the core temperature, for the first time. The quiescent luminosity at the equilibrium level of both these sources is quite typical of the quiescent emission from other ‘normal’ X-ray transients \cite[e.g. see fig. 5 in][]{Jonker2004} whose outbursts are not as long as those of either source and last usually for only weeks to months. For the core of KS 1731–260 and MXB 1659–29 to have a similar temperature, and hence quiescent luminosity, to the other X-ray transients then either the time-averaged mass accretion rate has to be similar to the other X-ray transients, or enhanced levels of core cooling are required. For the time-averaged mass accretion rates to be similar to other X-ray transients this would require extremely long periods of quiescence of the order of hundreds to thousands of years if the observed outbursts are typical. For MXB 1659–29 there was only a period of 21 years between outbursts and both known outbursts lasted for several years. The long-timescale accretion history for KS 1731–260 is less clear with only one outburst having been observed, however, extremely long quiescent periods are hard to explain with disk instability models \cite[e.g.][]{Lasota2001}. The measurement of the equilibrium level for both these sources confirms the previous findings by \cite{Wijnands2002a,Wijnands2003} from initial monitoring that enhanced core cooling processes are required for these sources.

Comparing the e-folding timescales of the two sources, we find that KS 1731–260 cools at a faster rate than MXB 1659–29 (by a factor of \sim 1.5), suggesting that the heat conductivity of the crust in KS 1731–260 is greater than that in MXB 1659–29. This interesting difference is likely due to differences in the properties of the crust between the two sources. In the \cite{Rutledge2002} models this would mean that KS 1731–260 has less impurities in the crust compared to MXB 1659–29 as a pure iron crust has a higher conductivity than one containing heavier metals also. However, one might expect the opposite to be the case, given that KS 1731–260 was actively accreting for 5 times longer than MXB 1659–29.

Given that we now have accurate cooling curves for these sources, and know the equilibrium level temperature, which places limits on the long-term time-averaged mass accretion rate, theoretical models need to be fit to this data to determine how high the thermal conductivity needs to be and what levels of neutrino emissions are really needed, or any alternative properties that can account for the rapid cooling of the crust. As more than one outburst has been observed for MXB 1659–29, and because the cooling curve is much better constrained, we suggest that this source is possibly a better object to determine accurate theoretical cooling curves for than KS 1731–260.

Although some neutron-star transients do not require enhanced core cooling to explain their quiescent luminosity \cite[e.g.][]{AqlX1,AU1608}, XTE J2123–058 (assuming the recurrence timescale is >70 years, \cite{Tomsick2004}) and SAX J1748.8–2021 in the globular cluster NGC 6440 \cite{Cackett2003}, there are several neutron-star transients in addition to KS 1731–260 and MXB 1659–29 that require either very low-time-averaged mass accretion rates or enhanced core cooling to explain their quiescent luminosity \cite[e.g.][]{CenX4,CX1905,X1732,Campana2002}. For KS1731 and XTE J2123–058 (assuming the recurrence timescale is 200–700 years, Tomsick et al. 2005) and 1H 1905+000 \cite{Jonker2008}, the only faint quiescent sources include the millisecond X-ray pulsars SAX J1808.4–3658, RX J170930.2–263927, RX J170930.2–263927, SAX J1810.8–2609, EXO 1747–214, RX J1808.4–3658 and 1H 1905+000. While the quiescent luminosity of KS 1731–260 and MXB 1659–29 is comparable to many quiescent neutron star transients, it is significantly higher than the emerging group of quiescent neutron star transients that are very faint in quiescence, with quiescent luminosities of less than 10^{32} ergs s^{-1}. Although these faint quiescent sources include the millisecond X-ray pulsars SAX J1808.4–3658, RX J0929–314, XTE J1751–305, RX J170930.2–263927, RX J170930.2–263927, SAX J1810.8–2609, EXO 1747–214, RX J1808.4–3658 and 1H 1905+000, the only other quasi-persistent source to have gone into quiescence
is X1732−304 in the globular cluster Terzan 1. Using recent \textit{Chandra} observations of Terzan 1 \cite{Cackett+03} we find that the most likely quiescent counterpart to this source has a 0.5−10 keV luminosity of \(2.6 \times 10^{32}\) ergs s\(^{-1}\), about 6 years after the end of an outburst that lasted at least 12 years. For comparison, the 0.5−10 keV luminosities of the last observations of KS 1731−260 and MXB 1659−29 are \(2.8^{+0.8}_{-0.6} \times 10^{32}\) ergs s\(^{-1}\) and \(7.5^{+2.7}_{-2.4} \times 10^{31}\) ergs s\(^{-1}\) respectively. Therefore, KS 1731−260, MXB 1659−29 and X1732−304 all have higher quiescent luminosities than 1H 1905+000. However, 1H 1905+000 was observed much longer after the end of its outburst then any of the other 3 sources. While the difference in quiescent luminosity may suggest that these sources will continue to cool further over the next several decades, it is more likely due to differing long-term time-averaged mass accretion rates or neutron star properties. The differences in the properties of quiescent neutron star transients need to be explored further by additional observations to determine why some sources require enhanced core cooling and why some sources are much fainter than others. Observations of the next quasi-persistent neutron-star transient sources to return to quiescence (EXO 0748−676 and GS 1826−238 are both quasi-persistent sources that are still active) will help determine whether a decline in flux and temperature to a constant level on the timescale of years, rather than decades, is typical.

We used an absorbed neutron star atmosphere model to fit to the data. If we use simple blackbody model in the spectral fitting instead, we get similar cooling curves, yet with different temperatures due to the differences between the shapes of blackbody and neutron star atmosphere spectra. When performing the spectral fits to both sources the normalisation of the neutron star atmosphere component was fixed to the distance of the sources. Unfortunately, these distances are quite uncertain, thus, if the distances are wildly incorrect. However, if the normalisation is left free when fitting, then the uncertainty in this parameter dominates the errors in the other parameters. Importantly, the timescale of the decrease in the temperature and flux of these sources should be unchanged by a different distance, only the absolute values of the temperature and flux will change. If the sources are much closer than assumed then the temperature measured will be lower and the column density higher, and the opposite if the sources are further away, as demonstrated by \cite{Wijnands+04}, who fit the first three \textit{Chandra} observations of MXB 1659−29 assuming 3 different distances to the source ranging from 5−13 kpc.

While we have interpreted the observations of KS 1731−260 and MXB 1659−29 in terms of the crust and core cooling model there are alternative models to explain quiescent neutron star emission including residual accretion or pulsar shock emission \cite{Campana+98a, Menou+99, Campana+00, Menou+00}. While these are often used to explain the power-law tail present in the spectra of some neutron star transients, residual accretion can produce soft spectra if accretion occurs onto the neutron star surface \cite{Zampieri+93}. However, while variations in the luminosity of the sources in quiescence can be explained by changes in the accretion rate or the amount of matter interacting with the magnetic field, our observations show that this would have to decrease exponentially in a smooth manner over a period of several years. Given that at the end of the outbursts of ‘normal’ short-duration neutron-star transients they reach their quiescent states within weeks \cite[e.g.][]{Campana+98a, Jonker+03} and that variations in accretion rate are generally not smooth, these alternative models seem unlikely.

We note that from the initial observations of both sources it was found that a power-law component (which is often attributed to residual accretion) in addition to the neutron star atmosphere component was not required to fit the spectra \cite{Wijnands+01a, Wijnands+02a, Wijnands+03, Wijnands+04}. While it has been observed that the contribution from the power-law component compared to the thermal component increases with decreasing quiescent luminosity below \(\sim 10^{33}\) ergs s\(^{-1}\) \cite{Jonker+04a}, the statistics of the last few observations are unfortunately not good enough to check for this. However, if residual accretion is occurring during quiescence it should be on-top of the ‘rock bottom’ thermal emission due to deep crustal heating \cite{Brown+98, Rutledge+2021} that we have now detected. Several neutron star transients have been observed to vary during quiescence e.g. Aql X−1, Cen X−4 and SAX J1748.8−2021 in the globular cluster NGC 6440 \cite{Rutledge+01L, Rutledge+02, Campana+03, Campana+04, Cackett+09}. This variability can be interpreted as a variable power-law component, possibly due to changes in the residual accretion rate or the amount of matter interacting with the magnetic field. Unfortunately this idea is hard to investigate with this data due to the low number of counts in the latter spectra. However, any variability in the flux from KS 1731−260 and MXB 1659−29 over the next few years around the base set by the thermal emission from the neutron star may indicate that some residual accretion is occurring.

APPENDIX A: RELATIONSHIP BETWEEN 
FLUX AND TEMPERATURE COOLING 
TIMESCALES

Assuming that the X-rays are due to some blackbody-type 
emission, then the flux, $F$, and temperature, $T$, and just 
simply related via 

$$ F = AT^4, \quad \text{(A1)} $$

where $A = \frac{R^2}{4\pi\sigma}$ and $R$ is the emitting radius, $D$ the dis- 
tance, and $\sigma$ the Stefan-Boltzmann constant. We are mod- 
elsing the cooling of the neutron star surface as an exponen- 
tial decay to a constant level, i.e., 

$$ T(t) = T_\infty + T'(t) \quad \text{(A2)} $$

where $T_\infty$ is the temperature at $t = \infty$ which we assume 
here to be constant, and $T'(t)$ describes the evolution of the 
temperature of the neutron star crust with time, which we 
model as:

$$ T'(t) = a \exp\left[-(t - t_0)/b\right], \quad \text{(A3)} $$

with $a$ a normalisation constant, $b$ the $e$-folding time, and 
t_0 the start time. Combining Eq. A1 and A2 leads to 

$$ F(t) = AT(t)^4 = AT_\infty^4 + AT'(t)^4. \quad \text{(A4)} $$

At the start of the cooling, when $T_\infty \ll T'(t)$, then the 
$T'(t)^4$ term dominates, and Eq. A3 becomes 

$$ F(t) \approx AT'(t)^4 = Aae^{-4(t-t_0)/b}. \quad \text{(A5)} $$

and there should be a factor of 4 difference between the $e$- 
folding times of $F$ and $T$. This was found to be the case for 
the initial cooling of MXB 1659−29 (Wijnands et al. 2004). 
However, further on in the cooling, once $T'(t) \sim T_\infty$, then 
the $e$-folding time of $F$ becomes a complicated function of 
the $e$-folding time of $T$ due to the constant term. Finally, 
once the cooling is negligible and $T'(t) \ll T_\infty$, then obvi- 
ously, $F(t) = AT_\infty^4$. 

---
