By using scanning tunneling microscopy (STM) we find and characterize dispersive, energy-symmetric in-gap states in the iron-based superconductor FeTe$_{0.55}$Se$_{0.45}$, a material that exhibits signatures of topological superconductivity, and Majorana bound states at vortex cores or at impurity locations. We use a superconducting STM tip for enhanced energy resolution, which enables us to show that impurity states can be tuned through the Fermi level with varying tip-sample distance. We find that the impurity state is of the Yu-Shiba-Rusinov (YSR) type, and argue that the energy shift is caused by the low superfluid density in FeTe$_{0.55}$Se$_{0.45}$, which allows the electric field of the tip to slightly penetrate the sample. We model the newly introduced tip-gating scenario within the single-impurity Anderson model and find good agreement to the experimental data.

he putative $s_x$ superconductor FeTe$_{0.55}$Se$_{0.45}$ is peculiar because it has a low Fermi energy and an unusually low and inhomogeneous superfluid density$^{2-7}$. It has been predicted to host a topological superfluid and Majorana zero-mode states$^{8-10}$. These predictions have been supported by recent experiments: photoemission has discovered Dirac-like dispersion of a surface state$^{11}$ while tunneling experiments have concentrated on in-gap states in vortex cores, which have been interpreted as Majorana bound states$^{12,13}$ since the low Fermi energy allows to distinguish them from conventional low-energy Caroli-Matricon-de Gennes states$^{14}$.

In-gap states have a long history of shining light into the properties of different host materials, and have allowed to bring insight into gap symmetry and structure, symmetry breaking, or the absence of scattering in topological defects, to name a few$^{15-24}$. Impurity bound states have also been investigated in chains or arrays of magnetic impurities on superconducting surfaces where they can lead to Majorana edge-states$^{25-28}$. Interestingly, there have also been signatures of spatially varying chain or array of magnetic impurities on superconducting surfaces where they can lead to Majorana edge-states$^{25-28}$. In the case of FeTe$_{0.55}$Se$_{0.45}$, zero-bias in-gap resonances have become a primary way to identify Majorana bound states at magnetic impurity sites or in vortex cores. At impurity sites, robust zero-bias peaks have been reported at interstitial iron locations which suggest the presence of Majorana physics$^{29}$. In addition, very recently STM experiments reported signatures of reversibility between magnetic impurity bound states and Majorana zero modes by varying the tip-sample distance on magnetic adatoms$^{30}$. Interestingly, there have also been signatures of spatially varying in-gap impurity states$^{31,32}$ which are not yet understood.

Here we report the detection of in-gap states at sub-surface impurities, which are spatially dispersing, i.e., they change energy when moving away from the impurity site by a distance of $\Delta y$. The energy can also be tuned by changing the tip-sample distance (Ad). We argue that the most likely explanation of our observations involves a magnetic impurity state of the YSR type affected by the electric field of the tip. We show good agreement between our experimental findings and the single impurity Anderson model.

**Results**

Detection of a particle-hole symmetric in-gap state in FeTe$_{0.55}$Se$_{0.45}$. We use FeTe$_{0.55}$Se$_{0.45}$ samples with a critical temperature of $T_c = 14.5$ K. They are cleaved at $\sim 30$ K in ultra-high vacuum, and immediately inserted into a modified Unisoku STM at a base temperature of 2.2 K, for preventing surface reconstruction and contamination. To increase the energy resolution, we perform all tunneling experiments using a superconducting tip, made by indenting mechanically ground Pt-Ir tips into a clean Pb(111) surface. With the superconducting tip and leading order in the tunnel coupling, the current-voltage ($I-V$) characteristic curves are proportional to the convolution of the density of states of Bogoliubov quasiparticles in the tip and the sample

$$I(r, V) \sim \int D_d(\omega + eV)D_r(\omega)[f(\omega, T) - f(\omega + eV, T)]d\omega,$$

where $D_d(\omega)$ is the density of states of the quasiparticles in the sample (tip), $f(\omega, T)$ is the Fermi-Dirac distribution at temperature $T$ and $e$ is the electron charge. In such a superconducting tunnel junction the coherence peaks in the conductance spectra, $dI/dV(\omega, V)$, appear at energies: $\pm (\Delta + \Delta_0)$, where $\Delta_0$ is the quasiparticle excitation gap of the sample (tip). In addition, the energy resolution is far better than the conventional thermal broadening of $\sim 5 \mathrm{kT}$ ($k_B$ is the Boltzmann constant) since it is enhanced by the sharpness of the coherence peaks of $D_d$.

To obtain the intrinsic local density of states (LDOS) of the sample, $D_r(\omega, V)$, we numerically deconvolute our measured $dI/dV(\omega, V)$ spectra while retaining the enhanced energy resolution (for more details see Supplementary Note 1). For this, we use our knowledge of the density of states of the tip with a gap of $\Delta_t = 1.3$ meV from test experiments on the Pb(111) surface using the same tip.

Figure 1a shows a topography of the cleaved surface of FeTe$_{0.55}$Se$_{0.45}$ obtained with a Pb coated tip (see inset). Brighter (darker) regions correspond to Te (Se) terminated areas of the sample.

**Fig. 1** Scanning Tunneling Microscopy on FeTe$_{0.55}$Se$_{0.45}$ with a superconducting tip. a Atomically resolved topographic image ($z$-height map, 25 × 25 nm$^2$) of FeTe$_{0.55}$Se$_{0.45}$ cleaved surface acquired with a Pb coated Pt/Ir tip (see inset) at 2.2 K in ultra-high vacuum. Setup condition: $V_{\text{set}} = -8 \mathrm{mV}$, $I_{\text{set}} = -100 \mu \text{A}$. b, d, f Spatially averaged differential conductance spectra in the areas ($r_1$, $r_2$, $r_3$) marked by the black circles in a; no in-gap states. $r_2$: two in-gap resonances at $\pm 1.3$ meV. $r_3$: two sets of peaks symmetric in energy around the Fermi level. c, e, g Deconvolution of the spectra shown in b, d, f, respectively, provide information about the intrinsic LDOS of the sample in the indicated areas. In $r_2$, a zero-bias impurity state is recovered and in $r_3$ two in-gap states are observed. Setup conditions: b $V_{\text{set}} = 6 \mathrm{mV}$, $I_{\text{set}} = 1.2 \mu \text{A}$, d, f $V_{\text{set}} = 5 \mathrm{mV}$, $I_{\text{set}} = 2 \mu \text{A}$. Lock-in modulation is $f_{\text{mod}} = 30 \mu \text{V}$ peak-to-peak for all measured spectra.
cleaved surface which has a tetragonal crystal structure. Our samples exhibit no excess Fe atoms or clusters on the cleaved surface. Spatially resolved scanning tunneling spectroscopy shows that most locations have a flat gap, as shown in Fig. 1b, c. However, when we acquire spectra at specific points indicated by black circles (r1 and r2) in Fig. 1a, we find sharp in-gap states. Figure 1d–e and f–g shows such states, both in the raw data as well as in the deconvoluted results. The measured in-gap state is symmetric in energy, i.e., it is visible at ± E\text{ig} (Fig. 1g), or at the Fermi level, E\text{ig} = 0 (Fig. 1e). In the raw data (before numerical deconvolution) the states are located at energies ± (Δ\text{s} ± E\text{ip}) (see arrows in Fig. 1d and f) due to the use of the superconducting tip.

### Spatial dispersion of the in-gap state

In order to characterize the impurity in more detail we acquire a spatially resolved dl/dV (r, V) map in the area shown in Fig. 2a. Three energy layers of the deconvoluted map depicting the LDOS variations are shown in Fig. 2b–d. The LDOS exhibits a clear ring-shaped feature which eventually becomes a disk with smaller radius at the Fermi level. A spatial line cut profile along the red dashed line shown in Fig. 2b reveals two symmetric resonances around zero energy that extend over ~10 nm in space (Fig. 2e). Importantly, the energies of the in-gap states vary spatially as shown in the spatial cuts (Fig. 2e–g) obtained from the same conductance map. The dispersion of the in-gap states shows an X-shaped profile where the crossing point is indicated with r0 (Fig. 2a). In more detail, the state is at zero energy at r0, and then moves away from the Fermi level, before fading out slightly below the gap edge. We will show later that the character of this dispersion is dependent on the tip-sample distance, and that there can also be zero or two crossing points. By inspecting the topography at r0 we find no signature of irregularities, which points towards a sub-surface impurity defect as the cause of the observed in-gap peaks in the spectra. We note that these impurities are sparse; we found a total of 5 in a 45 × 45 nm² field-of-view. These all show the same characteristic dispersions, but the X point is estimated at different tip heights. For details, see Supplementary Note 7. Similar observations have been reported previously on FeTe0.55Se0.45, but without a clear energy cross at the Fermi level.

### YSR impurity states

Our observations are reminiscent of YSR states caused by magnetic impurities in conventional superconductors. When a single magnetic impurity is coupled to a superconductor with energy gap Δ via an exchange coupling J then the ground state of the many-body system depends on the interplay between superconductivity and the Kondo effect (described by the Kondo temperature T\text{K}). For Δ ≥ k\text{B}T\text{K} the superconducting ground state prevails (unscreened impurity) whereas for Δ < k\text{B}T\text{K} the Kondo ground state dominates (screened impurity). In each case, quasiparticle excitations above the ground state give rise to resonances symmetrically around the Fermi level inside the superconducting gap. In an STM experiment, this results in peaks in the conductance spectrum at the energy of the two YSR excitations which is determined by the product ν\text{i}f\text{iS}, where S is the impurity spin and ν\text{i}f the normal state density of states in the superconducting host (FeTe0.55Se0.45 in our case).

It is important to note that the s\text{sym} symmetry of the order parameter in FeTe0.55Se0.45 can lead to a very similar phenomenology between magnetic and potential scatterers. While in conventional s-wave superconductors, magnetic impurities are required to create in-gap (YSR) states, in s\text{sym} superconductors, sub-gap resonances can also occur for non-magnetic scattering...
centers. This can be shown using different theoretical techniques, including T-matrix method\textsuperscript{40,41}, Bogoliubov-de Gennes equations\textsuperscript{42,43} and Green’s functions\textsuperscript{44–46} applied to multiband systems with $s_\pm$ symmetry. The similarity of magnetic and potential scatterers makes a distinction between these cases more challenging (but possible, with an external magnetic field\textsuperscript{30}). In either case, theory predicts energy-symmetric in-gap states with particle-hole asymmetric intensities.

The X-shaped phenomenology of the in-gap states shown above shares similarities with bound-states that have been observed in Pb/Co/Si(111) stacks\textsuperscript{47}, where they have been interpreted as topological\textsuperscript{47,48}. However, as we will show here, in our experiments the single point of zero bias is just one particular case of a manifold of dispersions that depend on the tip-sample distance.

**Tuning the energy of the in-gap state with the tip.** Figure 3a shows an intensity plot of a series of spectra above $r_0$, the location showing the zero-bias impurity state, with changing tip-sample distance (see inset for a schematic). We normalized each spectrum by the normal state resistance $R_N = V_{\text{set}}/I_{\text{set}}$. In order to reduce the distance, we control the tip in constant current feedback and increase the set-point for the current while keeping the voltage bias constant. In addition, we measure the tip-sample distance relative to the set-point: $V_{\text{set}} = 5 \text{ mV}$, $I_{\text{set}} = 0.4 \text{ nA}$. Strikingly, we observe a shift in the energy of the in-gap state with varying the tip-sample distance $\Delta d$. When the tip is brought closer to the sample surface, the sub-gap resonances shift towards the Fermi energy (Fig. 3b) where they cross and split again. We also point out that there is a strong particle-hole asymmetry in the intensity of the in-gap resonances. It can be clearly seen in Fig. 3b that the relative intensity between the positive ($p$) and negative ($n$) resonances ($I_p - I_n$) changes sign after the cross at the Fermi level. Further, we note that the energy shift for varying $\Delta d$ is stronger than the spatial dispersion. This can likely be explained by the tip shape, which can be approximated as a sphere of roughly 20 nm. As the tunneling current falls off exponentially with distance, one always tunnels to the point closest to the surface. However, the field is algebraic in the distance, and thus a change horizontally has less of an effect than a change vertically, as shown in Supplementary Note 5.

To obtain a more complete picture of the tuning of the in-gap states as we vary $\Delta d$, we measured five $dI/dV(r, V)$ maps (each at different tip-sample distance) and analyzed azimuthally-averaged radial profiles through the impurity center (Fig. 3c–d) shows two of these profiles. See Supplementary Note 3 for the other 3). We extract the energy of the resonances by Lorentzian fits (Fig. 3e), to observe that they cross the Fermi level at the impurity center when being close to the sample. This is the first time that such a crossing has been observed in an unconventional superconductor.

**Microscopic origin.** The important question that arises is: what tunes the impurity resonances that we observe? In previous experiments with magnetic ad-atoms or ad-molecules on conventional superconductors\textsuperscript{19,30}, it has been shown that the force of the tip changes the coupling between moment and substrate, and that the coupling $J$ and the YSR energy could be tuned in this way. In this case, when the energy crosses the Fermi level at the critical coupling $J_C$, a first-order quantum phase transition between the singlet (screened) and the doublet (unscreened) ground state is expected\textsuperscript{49,51}. Very recently, a similar force-based scenario has been reported in different systems involving magnetic ad-atoms on top of superconductors\textsuperscript{15}, including Fe(Te,Se)\textsuperscript{30}. As discussed in Supplementary Note 2, a similar scenario can in principle explain the sub-gap dispersion discovered here. However, as the impurity is not loosely bound on top of the surface in the present case, a movement between a sub-surface impurity and the superconductor due to the tip force as the cause for the tuning, seems unlikely. Therefore, we pursue alternative mechanisms. Motivated by the phenomenology of semiconductors\textsuperscript{52} or Mott insulators\textsuperscript{33}, where the tip can act as a local gate electrode (mediated by the poor screening), we propose a similar gating scenario for YSR states in the present case: the electric field of the tip can tune the energy of the impurity state and thus lead to a dispersing YSR state.

---

**Fig. 3 Energy dispersion of the sub-gap resonances as a function of the tip-sample distance.** a Conductance intensity plot for varying tip-sample distance ($\Delta d$) normalized by the normal state resistance $R_N$. The in-gap states disperse and cross at the Fermi level. Inset: schematic representation of the tip movement when we vary the tip-sample distance ($\Delta d$) and when the tip scans laterally ($\Delta y$ and $\Delta x$) at a constant height. b Same as in a for the deconvoluted LDOS data. Inset: schematic representation of the tip movement when we vary the tip-sample distance ($\Delta d$) relative to the set-point: $V_{\text{set}}$, indicates the radial offset $\sqrt{\Delta x^2 + \Delta y^2}$ from the impurity center ($\Delta r = 0$). c Energy of the impurity bound state for varying tip-sample distance, extracted by fitting a lorentzian curve in 5 intensity plots (see Supplementary Note 3) similar to c, d.
we expect that the details of the gating process depend on the tip that, similar to experiments on semiconductors and Mott insulators, maximum when the tip is right above the impurity. We emphasize the impurity location, we change the local electric dependence can be explained similarly: when moving the tip over leading to an energy shift of the in-gap resonances. The spatial screening (image charges method) to estimate that the shift is when the tip-sample distance is varied using a simple model for performing an estimate of the potential shift in the impurity, in this case supplied by temperature. For all panels we use \( U = 20 \), \( \Gamma_s = 3 \), \( \Gamma_I = 0.04 \), \( \gamma = \Gamma_s = 0.035 \) and \( k_B T = 0.2 \), all in units of \( \Delta_s \).

Fig. 4 Anderson impurity model for Yu-Shiba-Rusinov bound states. a Local density of states as a function of level energy \( \epsilon_0 \). The impurity spectral function was calculated within the zero-bandwidth approximation using the Lehmann spectral representation for the retarded Green’s function (see Supplementary Note 2). Red and blue lines indicate the two different \( \epsilon_0 \) sweeps plotted in b and c, respectively. b, c Relaxation dominated tunneling conductance calculated to leading order in the tip-impurity tunneling rate \( \Gamma_s \). Labels in b refer to processes in d. The dashed line in c shows the turning point of the blue line in a. d Guide to the eye for different conductance contributions in b and c. Processes 2-3 require a finite population of the excited state, in this case supplied by temperature. For all panels we use \( U = 20 \), \( \Gamma_s = 3 \), \( \Gamma_I = 0.04 \), \( \gamma = \Gamma_s = 0.035 \) and \( k_B T = 0.2 \), all in units of \( \Delta_s \).

Gate-tunable single impurity Anderson model. We model the sub-gap state as a YSR state arising from the magnetic moment of a sub-surface impurity level, whose energy is effectively gated by the tip-induced electric field. It should be noted that the sub-gap states arising in an \( s_s \)-wave superconductor from a simple non-magnetic impurity can produce a dispersive cross in the in-gap energies as a function of the impurity potential. However, this is only true for a particular range of potentials, and will not generally trace out a single dispersive cross as a function of the impurity strength\(^{12,44}\). Therefore, we are led to conclude that the impurity at hand involves a finite magnetic moment. Local impurity-induced magnetic moments may indeed be particularly prominent in correlated systems like FeSe where even non-magnetic disorder, in conjunction with electron interactions, can generate local moments\(^{56}\). Because of the magnetic nature of the impurity site, the results of our calculations are qualitatively independent on whether we treat the system as an \( s \) or \( s_s \)-wave superconductor. For simplicity, we perform our calculations assuming standard \( s \)-wave pairing.

The superconducting single impurity Anderson model\(^{57}\) involves an impurity level \( \epsilon_0 \) with charging energy \( U \) coupled via a tunneling rate \( \Gamma_s \) to a superconducting bath with energy gap \( \Delta_s 58-60\). We represent the sample by a simple \( s \)-wave Bardeen–Cooper–Schrieffer (BCS) superconductor, and use the zero-bandwidth approximation, including only a single spin-degenerate pair of quasiparticles at energy \( \Delta_s \)\(^{59,61}\). We further assume that the gating from the tip changes the impurity level \( \epsilon_0 \) linearly with distance. We then obtain the YSR states by calculating the local impurity spectral function, \( D_I(\omega, \epsilon_0) \), as a function of \( \epsilon_0 \) (and thus of gating) using the Lehmann representation (see Supplementary Note 2 for details). The result is plotted in Fig. 4a, where the observed crossing of the sub-gap states indicates a change between singlet, and a doublet ground state\(^{62}\). From the spectral function we can determine the current using leading-order perturbation theory in the tunnel coupling...
connecting the impurity to the tip, \( t_i \):

\[
I(V) = \frac{e(t_i)^2}{h} \int D_i(\omega) \frac{D_i(\omega)}{\omega} f(\omega, E) f(\omega + eV, T) - f(\omega + eV, T) d\omega,
\]

(2)

here \( D_i(\omega) \) is the spectral function of the superconducting tip with a finite quasiparticle broadening incorporated as a Dynes parameter, \( \gamma_i \) and \( \hbar \) the reduced Planck's constant. A phenomenological relaxation rate, \( \Gamma_i \), is incorporated into the Lehmann representation, (see Supplementary Note 2), to construct \( D_i(\omega, \gamma_i) \). This parameter accounts for quasiparticle relaxation of the YSR resonances at \( \omega = \pm E_{\text{gs}} \). The validity of the expansion in \( \Gamma_i = \tau_i |I'_i|/\hbar \), which captures only single electron transport and omits Andreev reflections, rests on the assumption that the sub-gap state thermalizes with rate \( \Gamma_i \) between each tunneling event. In the opposite limit, \( \Gamma_i \gg \Gamma_s \), transport takes place via resonant Andreev reflections, and the sub-gap conductance peaks at \( eV = \pm (\Delta_i + E_{\text{gs}}) \) display a bias asymmetry that is reversed compared to the bias asymmetry of the single electron transport regime.\(^{39} \) In principle, these two regimes can be differentiated by varying \( \Gamma_i \), since the conductance peaks increase linearly with \( \Gamma_i \) in the single electron regime, and sublinearly in the resonant Andreev regime.\(^{39,64} \) The experimental data shown in Fig. 3 display a marked asymmetry, consistent with our assumption of relaxation dominated transport where Andreev asymmetry will follow the asymmetry of the underlying spectral function.

Next, we investigate the situations where the tip moves over the impurity along the surface, or towards the impurity as a function of tip-sample distance \( \Delta d \). These situations are marked with blue and red arrows in Fig. 4a, respectively. In Fig. 4b, c we then plot sub-gap conductance as a function of level position, \( e\rho \), corresponding to the red/blue traces, assuming a linear dependence of \( e\rho \) with tip-sample distance. The agreement between our model and the data is good, both in terms of the energy dispersion and the asymmetry. Also, in both experiment and theory, additional conductance peaks at \( eV = \pm (\Delta_i - E_{\text{gs}}) \) are visible close to the singlet-doublet phase transition. We interpret these lines as the additional single electron processes shown in Fig. 4d, which arise from thermal population of the excited state close to the phase transition where \( E_{\text{gs}} \lesssim k_B T \). The conductance peaks at \( \Delta_i \pm E_{\text{gs}} \) meet at the point where the YSR states cross zero energy, signaling the change between singlet, and doublet ground states, and the asymmetry in intensity between the conductance peaks at \( eV = \pm (\Delta_i + E_{\text{gs}}) \) switches around.

The good agreement between this simple model (Fig. 4b, c) and the data presented in Fig. 2e and a, supports our interpretation that the tip exerts an effective gating of the impurity. We discuss alternative scenarios further in Supplementary Note 2, but the fact that our impurity is below the surface and the excellent agreement between the model and the data lead us to conclude that the gating scenario is most likely in the present case.

In summary, we have reported on the properties of energy symmetric in-gap states in FeTe\(_{0.55}\)Se\(_{0.45}\) that can be tuned through the Fermi level. These states extend over a large (~10 nm) area around the center locations. Our data point towards a sub-surface magnetic impurity embedded in a low-density superfluid with large screening length that leads to YSR-like in-gap states. We propose a novel tip-gating mechanism for the dispersion and perform calculations within the single impurity Anderson model that show excellent agreement with the data. Such a mechanism could also play a role in previous experiments on elemental superconductors or heterostructures. How such states are related to the topological superconductivity in FeTe\(_{0.55}\)Se\(_{0.45}\) remains an open question. Our work further shows that one needs to be careful when interpreting zero-bias peaks in putative topological states, and junction resistance dependent experiments are a necessary—ideally combined with other techniques such as noise spectroscopy,\(^{65-67} \) (see also Supplementary Note 4), spin-polarized STM,\(^{68} \) or photon-assisted tunneling,\(^{69} \) will allow for better understanding. Independent of this, tunable impurity states like the one we report here could offer a platform to study quantum phase transitions, impurity scattering, and the screening behavior of superfluids.

### Methods

**Sample preparation.** The FeTe\(_{0.55}\)Se\(_{0.45}\) single crystal samples were grown using the Bridgman method and show a critical temperature of \( T_c = 14.5 \) K. We cleave them at ultra-high vacuum (\( P_{\text{base}} \approx 1 \times 10^{-10} \) mbar) and low temperature (~30 K) and immediately insert them to our pre-cooled STM (USM-1500, Unisoku Co., Ltd). The STM tips used in this work are mechanically sharpened Pt-Ir wires. They are Pb-coated by indenting them on a Pb(111) surface which was first cleaned by repetitive cycles of Ar sputtering (\( P_{\text{base}} \approx 5 \times 10^{-5} \) mbar) followed by thermal annealing.

**Measurement.** Standard lock-in technique is employed for the tunnelling conductance measurements at 887 Hz. All measurements were performed at 2.2 K.

The Center for Quantum Devices is funded by the Danish National Research Foundation. D. Cho was supported by the National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIT) (No. 2020R1C1C1007995 and 2017R1A5A1014862) and the Yonsei University Research Fund of 2019-22-0209. A.A. acknowledges the support of the Max Planck-POSTECH-Hsinchu Center for Complex Phase Materials, and financial support from the National Research Foundation (NRF) funded by the Ministry of Science of Korea (Grant No. 2016K1A4A01922028).

Author contributions
D. Chatzopoulos, D. Cho, and K.M.B. performed the experiments and data analysis. D. Chatzopoulos, G.O.S., D.B., A.A., J.P., and B.M.A. performed the simulations. G.G. grew and characterized the samples. All authors contributed to the interpretation of the data and writing of the manuscript. M.P.A. supervised the project.
