Abstract

A literature review was carried out to identify pre and perinatal characteristics associated with variation in Apgar scores in population-based studies. The parameters identified in the literature search were included in the classical twin design study to estimate effects of pre and perinatal factors shared and nonshared by twins and to test for a contribution of genetic factors in 1- and 5-min Apgar scores in a large sample of Dutch monozygotic (MZ) and dizygotic (DZ) twins. The sample included MZ and DZ twins (N = 5181 pairs) recruited by the Netherlands Twin Register shortly after birth, with data on prenatal characteristics and Apgar scores at first and/or fifth minutes. The ordinal regression and structural equation modeling were used to analyze the effects of characteristics identified in the literature review and to estimate genetic and nongenetic variance components. The literature review identified 63 papers. Consistent with the review, we observed statistically significant effects of birth order, zygosity and gestational age (GA) for 1- and 5-min Apgar scores of both twins. Apgar scores are higher in first-born versus second-born twins and DZ first-born versus MZ first-born twins. Birth weight had an effect on the 5-min Apgar of the first born. Fetal presentation and mode of delivery had different effects on Apgar scores of first- and second-born twins. Parental characteristics and chorionicity did not have significant main effects on Apgar scores. The MZ twins' Apgar correlations equaled the DZ Apgar correlations. Our analyses suggest that individual differences in 1- and 5-min Apgar scores are attributable to shared and nonshared pre and perinatal factors, but not to genotypic factors of the newborns. The main predictors of Apgar scores are birth order, zygosity, GA, birth weight, mode of delivery and fetal presentation.

Keywords: Twin study; Apgar score; twin delivery; prenatal; perinatal; heritability; chorionicity

(Received 12 April 2019; accepted 18 April 2019)

The Apgar score is an important indicator of a newborn’s health and is established immediately after birth (Apgar, 1953). Apgar scoring is standard in obstetrics and neonatological practice, and the advantage of this screening tool is that it allows for prompt standardized assessment (Apgar, 1953; Committee on Obstetric Practice American Academy of Pediatrics — Committee on Fetus and Newborn, 2015). It has proven its utility as a population-level indicator of outcome risk, with predictive value for neonatal and infant death and post-neonatal development (Apgar, 1966; Drage et al., 1964; Harrington et al., 2007; Nelson & Ellenberg, 1981). Its value has been confirmed in national register studies (Casey et al., 2001; Grunebaum et al., 2013; Iliodromiti et al., 2014; Li et al., 2013; Straube et al., 2010; Thorngren-Jerneck & Herbst, 2001) and is recognized by national guidelines and the World Health Organization (Siddiqui et al., 2017; WHO, 2012). However, there is a discussion regarding other, possibly more precise, monitoring tools (O’Donnell et al., 2006; Rudiger et al., 2015). Apgar scores are evaluated at the first and fifth minutes after birth. While a low first-minute score is often transitory, persistence of poor health, resulting in a low fifth-minute score, often implies complications of clinical importance and indicates that the newborn has not responded to initial intervention (Drage et al., 1964; Harrington et al., 2007; Kattwinkel et al., 2010; Siddiqui et al., 2017; Thorngren-Jerneck & Herbst, 2001).

The assessment of Apgar scores in twins was first presented by Virginia Apgar in 1953. For twins, the Apgar score of the first-born twin typically was better than that of the second-born twin (Apgar, 1953). Replication studies of differences among first- and second-born twins (Haest et al., 2005; Herbst & Kallen, 2008; Morley et al., 1989; Wen et al., 2004), among twins and singletons (Hegyi et al., 1998; Thorngren-Jerneck & Herbst, 2001), among term and preterm newborns (Dolgun et al., 2016; Morley et al., 1989) and among different presentation and modes of delivery (Rossi et al., 2011) followed this initial work. Two small studies (Franchi-Pinto et al., 1999; Riese, 1990) suggested that genetic factors also contribute to variation in Apgar scores. However, because of small sample sizes, the results of these studies were inconclusive.

The aim of the present study is twofold. First, we present a literature review of studies of Apgar scores, including singleton and multiple births, to identify pre and perinatal characteristics associated with variation in Apgar scores in population-based studies. Second, in a large sample of Dutch monozygotic (MZ) and dizygotic (DZ) twins enrolled in the Netherlands Twin Register (NTR) (van Beijsterveldt et al., 2013), we estimated effects of pre and perinatal factors shared and nonshared by twins, including the parameters identified in the literature search and test for a contribution of genetic factors in the classical twin design.

Methods

Literature Review

A review of the literature regarding pre and perinatal characteristics associated with Apgar scores was conducted in PubMed (MEDLINE), Web of Science, Embase and reference lists of retrieved articles. Search terms were ‘Apgar scores’ and ‘heritability’, ‘genetic effect’, ‘prenatal factors’, ‘twins’, ‘fetal presentation’, ‘mode of delivery’, ‘gestational age’ and ‘neonatal outcome’. Studies on specific clinical aspects of pregnancy and neonatology and on mortality and morbidity were excluded. We followed prior research on Apgar scores (Milsom et al., 2002; Sibony et al., 2006; Straube et al., 2010) and grouped pre and perinatal characteristics in the following categories — biological maternal and paternal factors, socioeconomic factors, mode of conception, gestational age (GA), pregnancy and delivery characteristics and newborn characteristics. The list of characteristics was included in an empirical study in which resemblance in MZ and DZ twins in a bivariate (1- and 5-min Apgar scores) model was evaluated.

Empirical Study in Twins: Data Collection

Data on Apgar scores and pre and perinatal characteristics were obtained from the NTR (van Beijsterveldt et al., 2013). The NTR recruits families with twins a few weeks to months after birth. Informed consent is obtained from parents. Surveys, including questions on pregnancy, birth and outcomes, were sent to mothers after registration of newborn twins.

Zygosity

For the majority of twin-pairs, genotyping for zygosity was based on a genome-wide single nucleotide polymorphism (SNP) array (Odintsova et al., 2018), or on genome-wide sets of microsatellites. Zygosity typing in earlier studies was based on smaller numbers of microsatellite markers, blood groups (van Dijk et al., 1996) or SNPs (van Beijsterveldt et al., 2013). For 27% of the same-sex pairs, zygosity was based on items about physical similarity and frequency of confusion of the twins by parents and strangers from later surveys that correctly determine zygosity in 93% of the cases (Rietveld et al., 2000). In 19% of the cases, zygosity was based on a single item, indicating how much the children look alike at age 2, which gives a correct determination of zygosity in 92% of the cases (Groen-Blokhuys et al., 2011). For the other same-sex pairs, zygosity was based on a single question from survey 1.

The sample comprised 5181 twin pairs born between 2005 and 2017. Of these, 1763 were MZ and 3418 were DZ (34% and 66%, respectively, reflecting population prevalence in the Netherlands). The data set includes complete information on zygosity, GA and time between birth of the first and second twins. One-min Apgar scores were available in 4947 pairs and 5-min Apgar were available scores in 4724 pairs. Both Apgar scores were available for 4623 pairs.

The study protocols were approved on March 16, 2004, by the Central Ethics Committee on Research Involving Human Subjects of the VU University Medical Center, Amsterdam; and May 25, 2017 (NTR-25-mei-2007). All participants provided informed consent.

Variables

Apgar scores were analyzed: (a) as a continuous variable (scores between 0 and 10); (b) as conventional categories (ordinal variables): Apgar values of 0–6 (low), 7–9 (intermediate) and 10 (high); a total score of lower than 7 is considered a source of concern (Committee on Obstetric Practice American Academy of Pediatrics — Committee on Fetus and Newborn, 2015).

Based on the literature review, we tested for the effects of birth order (first or second born), zygosity (MZ or DZ), sex (boys or girls), GA, birth weight, mother’s and father’s age at birth, mother’s body mass index (BMI) at birth, fetal presentation (head presentation: cephalic; breech and horizontal presentations: noncephalic), mode of delivery (vaginal and intervention with vacuum extraction, forceps or cesarean section), and intertwin delivery interval. For 1003 MZ twins, we had information on choriocity (van Beijsterveldt et al., 2016). Of these, 745 were monochorionic (MC) and 258 were dichorionic (DC).

Data Analyses

Frequencies and means. The data were analyzed using SPSS version 25. The frequencies of maternal, delivery and infant characteristics were obtained within each Apgar score category, for first- and second-born twins and for MZ and DZ pairs. Differences between continuous variables in MZ and DZ pairs were tested using ANOVA, comparisons between first and second born with paired t tests.

Fixed effect analysis. The role of maternal, pregnancy, delivery and infant characteristics were analyzed in the first- and second-born twin by ordinal regression. The significant characteristics included in genetic covariance structure (GCS) analysis of the twin data. Four variables (GA, fetal presentation, mode of delivery and birth weight) were selected for inclusion in the analyses of twin resemblance for 1- and 5-min Apgar scores.

Twin correlations. Twin (polychoric) correlations of ordinal Apgar scores in MZ and DZ twins were estimated in Mplus. MZ twins are genetically identical, while DZ twins share on average 50% of their alleles identical by descent (from their parents). The MZ correlation (rMZ) is expected to be greater than the DZ correlations (rDZ) if the phenotype is influenced by genes (rMZ > rDZ). The presence of shared environmental factors is suggested if the DZ correlation is larger than half the MZ correlation (rDZ > rMZ/2). Unshared environmental influences are present if the MZ correlation is less than 1 (Boomsma et al., 2002).

GCS modeling. We carried out GCS analyses of polychoric correlation matrices of the ordinal (3-point) 1- and 5-min Apgar scores using Mplus 6 (Muthen & Muthen, 2007). The analysis of ordinal data is based on the liability-threshold model (Falconer, 1993), in which the ordinal scores arise by imposing thresholds on a continuous (standard normal) liability dimension. The twin resemblance at the level of this dimension is expressed by the polychoric correlations. The thresholds are a function of frequencies of the ordinal Apgar values. Given the 3-point ordinal Apgar scores,
as there are two thresholds in GCS analysis, we first fitted models to estimate the polychoric correlation matrices in the MZ and DZ twins and to analyse the thresholds in the presence of the covariates. Subsequently, we fitted an ACE model (see below), in which the phenotypic polychoric correlations are model in terms of genetic and shared and unshared environmental effects. Parameter estimates were obtained by means of the weighted least squares estimation (the Mplus estimator WLSMV; Muthen & Muthen, 2007). Model comparisons were based on the comparison of model chi-square (goodness of fit) statistics, using the Mplus difference test procedure. The main aim of the GCS modeling was to assess the contributions of genetic and environmental influences to the phenotypic (co)variance matrix of the first- and fifth-minute Apgar scores, while correcting for relevant covariates. We fitted a bivariate ACE model, which included additive genetic (A), shared environmental (C) and unshared environmental effects (E). The results of the analyses provide us with the decomposition of the phenotypic variance of the 1- and 5-min Apgar scores and the decomposition of the phenotype covariance (1-min with 5-min Apgar scores) into genetic and environmental components. In fitting the bivariate ACE model, we used a chi-square difference test to test sex differences, zygosity difference and birth-order differences in the covariates. We also tested sex differences in the ACE variance components.

We first fitted a model in which the thresholds differed with respect to birth order (first- vs. second-born twin), sex and zygosity (see Table S2 in the Supplementary material). We tested whether the thresholds were equal in males and females (retaining birth order and zygosity-related differences), which was found to be the case, \( \chi^2(16) = 23.8, p = .09 \). We tested whether the thresholds were equal in MZ and DZ twins, but this was not the case, \( \chi^2(8) = 23.4, p = .003 \). So, in the model of choice, we estimated 16 thresholds: 2 for 1-min Apgar scores and 2 for 5-min Apgar scores, which were different for zygosity and birth order. In the model, the regression coefficients of the covariates differed with respect to birth order.

We fitted the bivariate ACE model next. In this model, we allowed for sex differences in the ACE covariance matrices. As the twin correlations are suggestive of a CE model (i.e., absence of additive genetic effects), we first tested whether we could fix the additive genetic parameters to zero. This was found to be the case: \( \chi^2(6) = 10.3, p = .11 \). In this CE model, we constrained the shared and nonshared parameters to be equal over sex and found sex differences in the shared and nonshared parameters to be absent, \( \chi^2(4) = 3.958, p = .41 \).

Results

Review of the Literature

The review of studies on characteristics associated with Apgar score included population-based and twin studies published from 1981 to 2018, with exclusion of studies that concern specific clinical groups (e.g., pre eclampsia, gestational diabetes), mortality and morbidity in newborns, and long-term outcomes associated with Apgar scores. Our literature search identified 63 studies, including studies of twins (see Table 1) and singletons (see Table S1 in the Supplementary material). The characteristics associated with Apgar scores may be summarized as:

Biological maternal and paternal factors. Maternal short stature (Camilleri, 1981; Svenvik et al., 2015), low maternal age <17 (X. K. Chen et al., 2007), high maternal age >40 years (Jahromi & Husseini, 2008; Straube et al., 2010) and high paternal age >55 years (Khandwala et al., 2018) were associated with low Apgar scores. However, Milsom et al. (2002) found no association of Apgar scores with maternal age. Higher mother’s BMI and maternal obesity were associated with low Apgar scores in some (Chen et al., 2010; Straube et al., 2010; Thorngren-Jerneck & Herbst, 2001), but not all studies (Kiran et al., 2005; Rode et al., 2005).

Socioeconomic factors. These were studied in European countries. Maternal occupation and single-parent status did not show an association with Apgar scores in the study of Straube et al. (2010). No significant association was found with employment status during pregnancy (Marbury et al., 1984; Milsom et al., 2002; Straube et al., 2010). Low Apgar scores were associated with single motherhood (Milsom et al., 2002), missing paternal demographic information (Tan et al., 2004), low level of mother’s education and manual work (Hemminki et al., 1990; Odd et al., 2008) and adverse social circumstances (Kalland et al., 2006).

Mode of conception. Two small studies reported an association of 5-min Apgar score with mode of conception (Daniel et al., 2000; Ramoglu et al., 2014). No significant difference was found in terms of the 1- and 5-min Apgar scores between twins who were conceived naturally and twins who were conceived with the aid of artificial reproductive technologies (Caserta et al., 2014; Fan et al., 2013; Koudstaal et al., 2000; Moise et al., 1998; Ochsenkuhn et al., 2003; Pourali et al., 2016).

Gestational age. Apgar scores were associated with both low and high GA. For results on low GA, see Caukwell and Murphy (2002), Dolgun et al. (2016), Erdemoglu et al. (2003), Hartley & Hitti (2005), Hegyi et al. (1998), Iliodromiti et al. (2014), Lindroos et al. (2018), Morley et al. (1989), Svenvik et al. (2015) and van der Ven et al (2014). For results on high GA, see Svenvik et al. (2015) and Thorngren-Jerneck & Herbst (2001).

Pregnancy characteristics. A multiple pregnancy is a risk factor for adverse outcomes, including low Apgar scores (Morley et al., 1989; Pourali et al., 2016; Svenvik et al., 2015; Thorngren-Jerneck & Herbst, 2001). This holds specifically for MC pregnancies (Hjorto et al., 2014; Lindroos et al., 2018) and DC pregnancies with discordant fetal weight (Vulic et al., 2017). Again, some studies failed to find an association with chorionicity (Machado et al., 2017). Even though maternal smoking is generally associated with negative outcomes in neonates, most studies found no significant association between Apgar scores and prenatal maternal smoking after accounting for other confounders (Gilman et al., 2008; Kalland et al., 2006; Milsom et al., 2002; Straube et al., 2010), although an association between mother’s smoking during the first trimester and low Apgar score was seen by Kallen (2001).

Delivery characteristics. Multiple deliveries were associated with adverse outcomes in the second-born twin (Haest et al., 2005; Herbst & Kallen, 2008; Kwon et al., 2011; Morley et al., 1989; Thorngren-Jerneck & Herbst, 2001; Usta et al., 2002; Wen et al., 2004). The intertwin delivery interval is an important determinant of the adverse effects on the second born (Erdemoglu et al., 2003; Hartley & Hitti, 2005; Hjorto et al., 2014; Kwon et al., 2011; Stein et al., 2008) as this interval is related to the risk of hypoxia, due to decreasing pO2 in the umbilical arterial blood. However, other studies showed that even a relatively long intertwin delivery interval was not associated with unfavorable Apgar scores (Algeri et al., 2008; Straube et al., 2010). No significant difference was found with employment status during pregnancy (Marbury et al., 1984; Milsom et al., 2002; Straube et al., 2010). Low Apgar scores were associated with single motherhood (Milsom et al., 2002), missing paternal demographic information (Tan et al., 2004), low level of mother’s education and manual work (Hemminki et al., 1990; Odd et al., 2008) and adverse social circumstances (Kalland et al., 2006).

| 38 Algeri et al. (2018) | Italy | 800 (400 pairs) | Diamniotic pregnancies | Not indicated | Intertwin delivery time |
| 39 Lindroos et al. (2018) | Sweden | 1054 (527 pairs) | Twin birth with different delivery interval (not high risk group) | 5 min | Lower birth weight, early GA, intertwin birth weight discordance >25%, chorionicity (MC ↓ for second born) |

Note: Studies are indicated with ** in the reference list.
Noncephalic (breech and horizontal) presentation at birth is associated with low Apgar score in singletons (Rees & Langhoff-Roos, 1999; Krebs et al., 2001; Vogel et al., 2014) and twins (Hartley & Hitti, 2005). After a vaginal delivery of a vertex first twin, nonvertex presentation of the second twin was associated with increased odds of a low 5-min Apgar score (Vogel et al., 2014). However, other studies found no support for an effect of presentation on the Apgar score of the second twin (Bjelic-Radisic et al., 2007; Caukwell & Murphy, 2002; Lindroos et al., 2018; Schmitz et al., 2008; Usta et al., 2002). Emergency interventions (vacuum extraction, forceps and urgent operative delivery) were associated with adverse outcomes, including low Apgar scores (Hjorto et al., 2014; Milsom et al., 2002; Rode et al., 2005). The risk of a low Apgar score given at planned vaginal delivery was much higher than the risk associated with a selective cesarean section in singletons (Hegyi et al., 1998; Krebs & Langhoff-Roos, 1999) and twins (Schmitz et al., 2008), especially in the second-born twin (Herbst & Kallen, 2008; Jhaeri & Nadkarni, 2016; Kwon et al., 2011; Usta et al., 2005; Wenczus et al., 2014). The effect of mode of delivery in twins was not supported by some studies analyzing different fetal presentation deliveries (Barrett, 2013; Fox et al., 2010; Sentilhes et al., 2007). Cesarean section was associated with low Apgar in the second twin following vaginal delivery of first twin (Sibony et al., 2006; Wen et al., 2004).

Newborn characteristics. Several studies found a positive association between birth weight and Apgar scores (Dolgun et al., 2016; Erdemoglu et al., 2003; Hegyi et al., 1998; Ladehoff et al., 1986; Lindroos et al., 2018; Stein et al., 2008; Throngrn-Jerneck & Herbst, 2001). However, Iliodromiti et al. (2014) found no association of birth weight and Apgar scores in the large population-based sample of more than 1 million births in Scotland. Birth weight discordance in twins is associated with low Apgar scores for the second born (Lindroos et al., 2018; Stein et al., 2008). On average, girls have higher Apgar scores than boys (Dolgun et al., 2016; Hegyi et al., 1998; Stevenson et al., 2000; Zhao et al., 2017).

Based on our literature review, we included the following risk factors in our analyses of the twin data: zygosity, chorionicity, birth order, GA, birth weight, sex, mother’s age and father’s age at birth, mother’s BMI at birth, mode of delivery and fetal presentation.

Descriptives and Apgar Scores in Twins

Proportions of newborn NTR twins in three categories of 1- and 5-min Apgar scores (low, intermediate and high) for first- and second-born twins are presented in Figure 1 (distribution in pairs, see Table S3 in the Supplementary material). In terms of the proportions, the first- and second-born twins do not differ greatly with respect to the 1-min Apgar scores. For instance, the proportion of intermediate 1-min Apgar score (7–9) is about 79%, 74%, 77% and 71% (MZ first born, MZ second born, DZ first born and DZ second born, respectively). There are, however, appreciable differences between the first- and second-born twins in the 5-min Apgar scores. For instance, the proportion of a high 1-min Apgar score (10) is about 71%, 40%, 72%, and 57% (MZ first born, MZ second born, DZ first born and DZ second born, respectively).

We compared the means of Apgar scores in MZ and DZ twin pairs between first- and second-born twins. Mean continuous Apgar scores were higher in the first born than in second-born twins in both MZ and DZ pairs: in MZ at first minute, 8.45 versus 8.1 (p < .0001), at fifth minute, 9.36 versus 9.22 (p < .0001); in DZ at first minute, 8.61 versus 8.03 (p < .0001), at fifth minute, 9.51 versus 9.26 (p < .0001). MZ first-born twins had lower Apgar scores than DZ first-born twins: at first minute, 8.43 versus 8.6 in DZ, at fifth minute, 9.36 versus 9.51 in DZ (p < .0001). In second-born twins there was no effect of zygosity (see Table S4 in the Supplementary material).

Next, we tested pre and perinatal characteristics for the first- and second-born twins. The distribution of perinatal and delivery characteristics of NTR twins are presented in Table 2 (for information on characteristics of low, intermediate and high Apgar score groups, see Table S5 in the Supplementary material). Given alpha of .05, mother’s age, father’s age, and mother’s BMI at birth did not predict Apgar scores (Table S6 in the Supplementary material). The intertwin delivery time was significant for Apgar scores of the second-born twin. There was no significant effect of chorionicity on Apgar score in MZ twins with chorionicity data, taking into account GA, birth weight, sex, mode of delivery and fetal presentation (Table S7 in the Supplementary material). (Continued)
Birth weight had a positive effect on 5-min Apgar score of the first born ($\beta_{1\text{min}} = 0.09$, effect on both Apgar measurements in both twins ($\beta_{5\text{min}}$) have negative effect on Apgar scores ($\beta_{1\text{min}} < 0$). The effects of delivery characteristics, such as mode of delivery and fetal presentation at birth, were different for first- and second-born twins. Noncephalic presentation of the second-born twin was more likely to have lower 1-min Apgar scores ($\beta_{1\text{min}} < 0$), and there were no mothers younger than 18. An effect of a maternal BMI on Apgar score was found in some studies of teenage mothers, and intertwin delivery time. In the current analyses of twins, birth order, zygosity, GA, birth weight, fetal presentation, birth weight and mode of delivery (characteristics of individual twins) as covariates. We estimated the effects of covariates and the polychoric twin correlations (Table S2 in the Supplementary material).

In multicovariate genetic analyses, the effects of covariates did not differ with respect to sex, $\chi^2 (16) = 8.88, p = .91$. GA had a positive effect on both Apgar measurements in both twins ($p < .0001$; Table 3). Birth weight had a positive effect on 5-min Apgar score of the first born ($\beta_{1\text{min}} = 0.09, p = .002$). The effects of delivery characteristics, such as mode of delivery and fetal presentation at birth, were different for first- and second-born twins. Noncephalic presentation at birth of the first-born twin had a positive effect on Apgar scores of the first born ($\beta_{1\text{min}} = 0.11, p = 0.02; \beta_{6\text{min}} = .19, p < .0001$) and noncephalic presentation of the second-born twin have negative effect on Apgar scores ($\beta_{1\text{min}} = -.23, p < .0001; \beta_{6\text{min}} = -.16, p < .0001$). First-born twins delivered vaginally were more likely to have higher Apgar scores at both points ($\beta_{1\text{min}} = .26, \beta_{6\text{min}} = .42, p < .0001$). Second-born twins delivered vaginally were more likely to have lower 1-min Apgar scores ($\beta_{1\text{min}} = -.14, p < .0001$), and the effect was not significant for the 5-min Apgar score ($\beta_{6\text{min}} = -.002, ns$).

Table 4 summarizes the twin correlations with and without the correction for covariates (see also Table S8 in the Supplementary material). Overall, the correlations, which varied between .43 and .55, did not differ greatly between zygosity, which suggests the absence of genetic effects. Shared environmental influences accounted for 52.6% (95% confidence interval (CI) [0.51, 0.54]) and 50.2% (95% CI [0.48, 0.52]) of the variance of the 1- and 5-min Apgar scores, respectively. The remainder of the variance was explained by nonshared environmental effects: 47.4% (95% CI [0.46, 0.49]) and 49.8% (95% CI [0.48, 0.52]) of the variance of the 1- and 5-min Apgar scores, respectively. The correlation between the 1- and 5-min Apgar scores was $0.70$ (95% CI $[0.68, 0.72]$), which is consistent with the correlations shown in Table 4. This correlation is decomposed into $0.33$ (95% CI $[0.30, 0.35]$) due to shared prenatal environmental factors, and $0.37$ (95% CI $[0.39, 0.40]$) due to unshared prenatal environmental factors (see Table S9 and Figure S1 in the Supplementary material).

### Discussion

Our literature review identified characteristics that were significantly associated with Apgar scores in population-based and twin studies. These included GA, birth weight, sex, mother’s and father’s age at birth, mother’s BMI, mode of delivery, and fetal presentation, specifically for twins’ zygosity, chorionicity, birth order and intertwin delivery time. In the current analyses of twins, birth order, zygosity, GA, birth weight, fetal presentation at birth and mode of delivery contributed to Apgar scores.

In our empirical study, parental characteristics were not associated with Apgar scores. The effects of mother’s and father’s age on Apgar scores as established in other studies may be explained by families included in these other studies, such as teenage mothers (X. K. Chen et al., 2007), mothers over age 40 (Jahromi & Husseini, 2008), and older fathers (Khandwala et al., 2018). In our sample, only 171 women were above 40 years (3.2% MZ and 3.4% DZ of mothers), and there were no mothers younger than 18. An effect of a maternal BMI on Apgar score was found in some studies of singletons (M. Chen et al., 2010; Straube et al., 2010; Thorngren-Jerneck & Herbst, 2001). Multiple pregnancies are generally accompanied by greater maternal BMI than in singleton pregnancies due to gestational weight gain. This may explain the nonsignificance of maternal BMI effect on Apgar score in our study (near 45% of mothers in our sample had BMI $>30$). Optimal gestational weight gain in twin pregnancy is unclear (Bodnar et al., 2014). However, some studies also support our findings that maternal age (Milsom et al., 2002) and BMI at birth (Kiran et al., 2005; Rode et al., 2005) are not associated with Apgar score. Monochorionicity was an important risk factor for adverse perinatal outcomes in twins (Dube et al., 2002; Hjorto et al., 2014; Lindroos et al., 2018).

### Table 2. (Continued)

| Mode of delivery | MZ twin pairs (1763) | DZ twin pairs (3418) |
|------------------|---------------------|---------------------|
|                  | First born          | Second born         | First born          | Second born         |
| Vaginal          | 970 (55.20%)        | 968 (55.50%)        | 1734 (50.90%)       | 1617 (47.80%)       |
| Planned cesarean section | 235 (13.40%) | 234 (13.40%)        | 650 (19.10%)        | 649 (19.20%)        |
| Urgent intervention (forceps, vacuum extraction) | 182 (10.40%) | 110 (6.30%)         | 314 (9.20%)         | 257 (7.60%)         |
| Urgent caesarean section | 370 (21.10%) | 431 (24.70%)        | 712 (20.90%)        | 863 (25.50%)        |
| Total            | 1,757               | 1,743               | 3410                | 3,386               |
| Missing          | 6                   | 20                  | 8                   | 32                  |
| Intertwin delivery time (min) |               |                     |                     |                     |
| <5               | 767 (43.50%)        | 1492 (43.70%)       |                     |                     |
| 6-15             | 612 (34.70%)        | 914 (26.70%)        |                     |                     |
| 16-60            | 342 (19.40%)        | 866 (25.30%)        |                     |                     |
| 61-1440          | 42 (2.40%)          | 146 (4.30%)         |                     |                     |
| Total            | 1,763               | 3,418               |                     |                     |

Note: Values are n (%).
van Beijsterveldt et al., 2016), but was not associated with Apgar scores in our study.

In accordance with many singleton (Hegyi et al., 1998; Iliodromiti et al., 2014; Svenvik et al., 2015; van der Ven et al., 2014) and twin studies (Caukwell & Murphy, 2002; Dolgun et al., 2016; Erdemoglu et al., 2003; Hartley & Hitti, 2005; Lindroos et al., 2018; Morley et al., 1989), we found a large effect of GA. In preterm newborns, a low Apgar score may indicate intrinsic physiological immaturity and inadequate capacity for response rather than abnormal physiological functions (Iliodromiti et al., 2014). Preterm twins have the same prognosis as preterm singletons (Morley et al., 1989). The effect of GA was stronger than birth weight. We found effects of birth weight on Apgar scores in first-born twins, but not in the second born.

Our findings on birth order agree with previous findings. The first twin is in better clinical condition (Franchi-Pinto et al., 1999; Haest et al., 2005; Herbst & Kallen, 2008; Kwon et al., 2011; Morley et al., 1989; Thorngren-Jerneck & Herbst, 2001; Usta et al., 2002; Wen et al., 2004). The second twin is at greater risk of lower scores, which can be due to longer delivery time, risk of hypoxia, nondefinable fetal presentation before birth to decide the better tactics or complications during delivery. The proportion of low Apgar score in first- and second born reported by Franchi-Pinto et al. (1999) corresponds with our findings.

### Table 3. Average for continuous Apgar scores and effect of GA, birth weight, fetal presentation and mode of delivery on ordinal 1- and 5-min Apgar score in first- and second-born twins

|                          | β    | SE   | Est./SE | p       | CI (95%)       |
|--------------------------|------|------|---------|---------|----------------|
| 1-min Apgar first-born twin: mean 8.45 |      |      |         |         |                |
| **Effect size for ordinal score** |      |      |         |         |                |

### Table 4. Twin correlations for 1- and 5-min Apgar score (ordinal variables) noncorrected and corrected for GA, birth weight, mode of delivery and fetal presentation

|                          |       | r adjusted to covariates |       |
|--------------------------|-------|--------------------------|-------|
| **Twin correlations1-min Apgar** |       |                          |       |
| MZM                      | .621  | .552                     |       |
| MZF                      | .607  | .537                     |       |
| DZM                      | .544  | .485                     |       |
| DZF                      | .610  | .551                     |       |
| DZMF                     | .539  | .479                     |       |
| DZFM                     | .595  | .536                     |       |
| **Twin correlations5-min Apgar** |       |                          |       |
| MZM                      | .676  | .540                     |       |
| MZF                      | .643  | .507                     |       |
| DZM                      | .630  | .518                     |       |
| DZF                      | .620  | .508                     |       |
| DZMF                     | .568  | .455                     |       |
| DZFM                     | .547  | .435                     |       |

Note: MZM = monozygotic male, MZF = monozygotic female, DZM = dizygotic male, DZF = dizygotic female, DZMF = dizygotic male-female and DZFM = dizygotic female-male.
Fetal presentation at birth showed opposite effects in first- and second-born twins and should be further investigated, together with mode of delivery and in application of horizontal/nonhorizontal classification of presentation. The positive effect of noncephalic presentation in first-born twins in our study is in contrast with other studies (Hartley & Hitti, 2005) and could be associated with tactics of delivery that can be planned in comparison with delivery of the second born. Delivery practice in the case of noncephalic presentation of the first born can increase the probability of high Apgar scores in the newborns. The previous studies have shown that the effect of fetal presentation on Apgar scores in the second born is associated with fetal presentation and mode of delivery of the first born (Bjelic-Radisic et al., 2007; Caukwell & Murphy, 2002; Lindroos et al., 2018; Schmitz et al., 2008; Usta et al., 2002; Vogel et al., 2014). Cephalic presentation of the second twin is associated with higher Apgar scores in our study, in line with previous studies.

Physicians have gained a clear understanding of how to deliver twins with regard to their presentation and gestation. Some retrospective analyses and meta-analyses reported that the prognosis of twins was not different according to delivery mode (Hogle et al., 2003; Sibony et al., 2006; Usta et al., 2002), but population-based studies reported that the mortality rate or complications in second twins were higher in vaginal deliveries (Herbst & Kallen, 2008; Jhaeveri & Nadkarni, 2016; Kwon et al., 2011; Rossi et al., 2011; Schmitz et al., 2008; Smith et al., 2002; Usta et al., 2005; Wen et al., 2004; Wenckus et al., 2014). We found better outcomes, in terms of Apgar score, for vaginal delivery in first-born twins and intervention delivery in the second born. We did not confirm that cesarean section is associated with low Apgar in second-born twins as shown by Wen et al. (2004). The mode of twin delivery should be considered on the basis of information on fetal presentation of both twins: the mode of delivery of the second born should take in account the mode of delivery of the first born.

To our knowledge, ours was the first large study evaluating genetic influences on 1- and 5-min Apgar scores. In contrast to a smaller twin study done without precise zygosity definition (Franchi-Pinto et al., 1999), we did not find evidence for genetic influences on Apgar scores. The slightly higher correlations in MZ twins in our study partly correspond with the intraclass correlation coefficients reported by Riese (1990) for 1-min Apgar scores in a small sample of MZ and DZ twins. We did observe large influences of nongenetic factors shared by twins from the same pairs. We acknowledge that a shared environmental component could reflect to some extent a shared measurement bias (e.g., if both twins are rated at the same time by one nurse). Apgar scores represent routine clinical practice, but some of the variability could reflect heterogeneity in clinical scoring practices as opposed to true differences in biomedical outcomes (Siddiqui et al., 2017). Also, the genotype of the mother in part creates the prenatal environment of both twins and thus is part of the ‘shared environment’.

Our data do not reflect the whole population as it does not include cases with infant death. If the individual components of Apgar score (skin color or appearance, pulse rate, reflex, activity and respiratory effort) were available for analysis, it is possible that the contribution of shared and nonshared environment and genetic influence would differ across components. Twin-specific in utero environment and epigenetic factors are also of interest for future studies to examine the sources of unique environment. For understanding the variance of shared and nonshared perinatal environment, further analysis of mother’s health status and early medical support is needed.

Conclusions

We have found that for both MZ and DZ pairs, second-born twins have lower Apgar scores in comparison with first-born twins. There are different effects of pre and perinatal characteristics on 1- and 5-min Apgar score in first- and second-born twins. Based on twin analyses, a genetic component was not significant for Apgar scores. For 1- and 5-min Apgar score, about half of the variation was explained by shared and half by nongenetical environmental factors. It is possible that some of the shared environment is due to the same rate scoring both twins. The most important factors for Apgar scores are GA, birth weight, birth order, zygosity, fetal presentation and mode of delivery.
